Chapter 1

Introduction

Carbon is the most fundamental building block of life on this planet and the fourth most abundant element in the universe. Of the global carbon reservoir, the vast majority of carbon is stored in carbonate rocks, where it has such a long residence time that it affects climate only on geological time scales (>100 kyear). The next most substantial portion is stored in fossil organic carbon deposits, of which only a small percentage is recoverable as fossil fuel. Other significant carbon stores, which are subject to fluxes over shorter time scales, include the oceans, atmosphere, and the terrestrial biosphere. With the onset of the Industrial Revolution at the end of the 18th Century, human beings have been rapidly releasing naturally, long-term stores of fossil organic carbon by combustion to carbon dioxide (CO₂) that is emitted into the atmosphere. Over the 20th Century the atmospheric CO₂ concentration increased by more than 20%, and the rate of increase is still rising. The Intergovernmental Panel on Climate Change (IPCC) predict atmospheric CO₂ partial pressure to be between 490 – 1,250 ppm by the end of the 21st Century, which would place concentrations at least ~190 ppm higher than has been seen in the past 100,000 years (Petit et al., 1999; Macfarling Meure et al., 2006). The consequences of the escalation of atmospheric CO₂ are not fully understood, thus we are now partaking in a, potentially very risky, global biogeochemical experiment.

1.1 Carbon dioxide in the ocean-atmosphere system

In geological history a close link has been observed between the climate and atmospheric CO₂ concentrations over the glacial-interglacial cycle (Petit et al., 1999). Prior to 1800 the atmospheric CO₂ concentration had been quite stable between 272 and 284 ppm (Macfarling Meure et al., 2006), at the peak of an inter-glacial period. Since then there has been an exponential increase in anthropogenically-produced CO₂ (Keeling and Whorf, 2004) with the current atmospheric concentration having just reached over 400 μ atm (Manoa Loa Observatory, <http://co2now.org/Current-CO2/CO2-Now/noaa-mauna-loa-co2-data.html>). Carbon dioxide is a *greenhouse* gas, meaning that it absorbs the sun's energy when it is emitted from the land as infrared radiation, thus trapping a portion of the sun's energy as heat within the atmosphere. A number of gases contribute to this process (e.g. H₂O, CH₄, N₂O), however, due to its sheer amount, CO₂ is the second overall most effective, after water vapor (Finlayson-Pitts and Pitts, 2000). The temperature increase is proportional to the enhanced radiative forcing caused by higher CO₂ concentrations. The effects of increasing temperatures include changes in precipitation patterns, a reduction in snow cover and sea ice, and an overall reduction in the effectiveness of the ocean to absorb anthropogenic CO₂.

It was proposed at the beginning of the 20th Century that a portion of the CO₂ produced from fossil fuel combustion was being taken up by the oceans, which has since proved to be the case. Of the total 300 Pg C (Pg = 10¹⁵g) that humankind has already released (Archer, 2005), it has been shown, through a variety of techniques, that approximately 40% has been taken up by the world ocean (Sabine, 2004), which currently amounts to approximately 120 PgC. The transfer of CO₂ from the atmosphere into the ocean is primarily driven by a simple thermodynamic flux, caused by the differential in partial pressure between the two mediums. At equilibrium the CO₂ in surface waters can be described by Henry's Law:

$$[\text{CO}_2] = K_0 \cdot f\text{CO}_2, \quad (\text{equation 1})$$

where K_0 is the solubility coefficient in seawater and $f\text{CO}_2$ is the fugacity of CO₂ in μatm . That is to say that when, due to continuing CO₂ emissions by mankind, the atmospheric $p\text{CO}_2$ is higher than the oceanic $p\text{CO}_2$, there will continue to be a flux into the ocean. In reality this $p\text{CO}_2$ equilibrium between the ocean and atmosphere is modified by winds, biological uptake and temperature, leading to large heterogeneity of surface ocean $p\text{CO}_2$ in different regions of the global ocean.

The accumulation of carbon dioxide in the oceans leads to the phenomenon known as *ocean acidification* (Doney et al., 2009; Raven, 2005). This term can be misleading, as the oceans will never become *acidic* (i.e. reach a pH below 7). In fact it refers more to the increase in proton (H^+) concentration and decrease in hydroxide ion (OH^-) concentration as a result of the formation and subsequent dissociation of carbonic acid. The uptake of anthropogenic CO₂ has already caused a drop of 0.1 pH units in surface ocean pH (Orr et al., 2005) and is estimated to cause a further reduction of ~0.3-0.5 by the end of the century (Caldeira and Wickett, 2005). The concurrent depletion in carbonate ion concentration is also predicted to have a detrimental effect on a number of calcifying organisms (Fabry et al., 2008) and is already having an impact in some areas of the Southern Ocean (Bedarnsk et al., 2012). Recent findings by Wootton et al. (2008) indicate that ocean acidification may be taking place at a faster rate than previously predicted in the coastal regions. Due to the large amount of primary production taking place in these regions it is becoming increasingly important to further our understanding of the fate of carbon in coastal and shelf systems.

1.2 Carbon dioxide in seawater

Of the combined ocean-atmosphere system 98% of the carbon is stored in the ocean (Zeebe and Wolf-Gladrow, 2001). The ocean acts as a very effective store of carbon due to the

behavior of the dissolved chemical carbon species. When carbon dioxide (CO₂) dissolves in water it forms carbonic acid (H₂CO₃), which is a weak, diprotic acid. It thus partially dissociates in solution, releasing one or two protons (H⁺) as shown in equations 2 and 3.

These equations represent a buffering system whereby further addition of carbonic acid, carbon dioxide, or carbonate shifts the respective equilibria towards the bicarbonate state, which is the dominant carbonate species in the pH range found in the oceans. The K₁ and K₂ are the acid dissociation constants of carbonic acid, which can be defined by the following two equations:

$$K_1 = [\text{HCO}_3^-][\text{H}^+]/[\text{H}_2\text{CO}_3] \quad (\text{equation 4})$$

$$K_2 = [\text{CO}_3^{2-}][\text{H}^+]/[\text{HCO}_3^-] \quad (\text{equation 5})$$

These dissociation constants, sometimes referred to in the logarithmic form as pK₁ and pK₂, are heavily dependent upon salinity, temperature and pressure. One of the challenges of quantifying the carbonate system is that many of the chemical species cannot be directly measured and thus must be indirectly calculated using the aforementioned equations.

There are four measurable carbonate parameters: total alkalinity (TA, A_T), dissolved inorganic carbon (DIC, C_T), pH and pCO₂. The latter two provide direct concentrations of [H⁺] and [CO₂(aq)*], where the * represents a combination of CO₂(aq) and H₂CO₃, as the two species can not be analytically differentiated. The definitions of these four parameters are as follows:

$$\begin{aligned} A_T = & [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}] + [\text{B(OH)}_4^-] + [\text{OH}^-] + [\text{HPO}_4^{2-}] + 2[\text{PO}_4^{3-}] + \dots [\text{H}_3\text{SiO}_4^-] + \dots \\ & [\text{NH}_3] + [\text{HS}^-] + \dots - [\text{H}^+] - [\text{HSO}_4^-] - [\text{HF}] - [\text{H}_3\text{PO}_4] - [\text{HNO}_2] + \dots \quad (\text{Dickson, 1981}). \end{aligned}$$

(equation 6)

$$\text{DIC} = \sum [\text{H}_2\text{CO}_3] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}] \quad (\text{equation 7})$$

$$\text{pH} = -\log_{10}[\text{H}^+] \quad (\text{equation 8})$$

$$\text{pCO}_2 = x(\text{CO}_2) \cdot p, \quad (\text{equation 9})$$

where $x(\text{CO}_2)$ represents the mole fraction of CO_2 and p represents the pressure of equilibration. From any two of these measured variables, with complementary hydrographic data and K_1 and K_2 parameterizations, it is possible to calculate the other two variables. Where more than two parameters are determined it becomes possible to assess how *internally consistent* the system is (i.e. how well the calculated values represent the measured values). A number of studies into this have demonstrated that significant differences are obtained when using different determinations of the dissociation constants. These differences are frequently larger than the error associated with measuring them, as such, measuring as many parameters as possible is generally favorable. The lack of ideal closure in the carbonate system remains an issue in the inorganic marine carbon community (see Chapter 2).

The vast majority of inorganic carbon in seawater is riverine in origin, accumulated downstream from the chemical weathering and dissolution of carbonate rocks. Due to the dominance of the carbonate and bicarbonate ions in the alkalinity equation, this chemical weathering and dissolution also represents the dominant supply of total alkalinity to the ocean. A result of this is that in coastal regions with strong riverine influence there is a strong negative correlation between salinity, DIC and A_T . In contrast, in the surface waters of the open ocean this relationship is reversed, as the conservative nature of DIC, A_T mean that they are influenced in the same way as salinity to physical processes, such as, mixing and evaporation, leading to a tight co-correlation. In the presence of biological activity however, both parameters can show substantial deviations from conservative behavior.

The DIC is taken up by phytoplankton in photosynthesis and, in some organisms, for the formation of calcium carbonate. It can similarly be released in the respective reverse processes of respiration and dissolution, as shown in the equations below.

Depending on the amount of phytoplankton present, the process of photosynthesis can lead to large deficits of DIC in surface waters and a lowering of $p\text{CO}_2$ causing a subsequent flux of CO_2 from the atmosphere into the ocean. The majority of the biologically sequestered carbon is released back into the water column following respiration by bacteria. The amount

of carbon that is transported into deeper water layers and ultimately to the seafloor depends on a number of factors, such as, the phytoplankton class group (Jin et al., 2006; Klaas and Archer, 2002), and the depth of the water column (Reimer et al., 1999; Beck and Brumsack, 2012). Further degradation takes place in the sediment, through the following series of electron acceptors: O_2 , SO_4^{2-} , MnO , $FeOOH$, H_2S and CO_2 (Mackin et al., 1989). The ratio of remineralization which takes place in the water column compared to the sediment is largely dependent on the depth of the water column, and ranges from 99% in the open ocean (Dunne et al., 2007) to 30% in the German Bight (Reimer et al., 1999) and 50% in the Wadden Sea (van Beusekom et al., 1999).

The formation and dissolution of calcium carbonate helps to regulate the carbonate system on much longer time scales (Archer, 2005). There are two forms of calcium carbonate; aragonite and calcite. Calcite is the more stable form and thus the depth at which dissolution rapidly increases (chemical lysocline) is approximately 2km deeper than that of aragonite in the Atlantic Ocean. Above this depth, the formation of $CaCO_3$ is the dominant process due to the presence of calcifying phytoplankton and zooplankton. At greater depths a combination of increasing pressure, lower temperatures and decreasing pH leads to the dissolution of $CaCO_3$. Despite this general trend, the analysis of high-quality A_T data from the Atlantic has also shown that a significant proportion of $CaCO_3$ dissolution occurs at depths shallower than the chemical lysocline (Chung et al., 2003). Shallow water dissolution is potentially significant as the generation of A_T in surface waters helps to buffer the changes in the carbonate system caused by increasing pCO_2 . However, in shelf systems it has been shown that shallow water $CaCO_3$ dissolution is much less significant compared to the A_T produced from other processes, such as sulfate reduction (Chen, 2002).

In contrast to DIC and A_T , pH and pCO_2 show great variability with temperature and pressure changes, making them ideal to monitor smaller, and short term, variations in surface waters. Normally pH and pCO_2 show a strong anti-correlation to one another due to the associated decrease in pH with increasing CO_2 concentrations. For these reasons A_T and DIC are the preferred parameters to measure for deep ocean work, whereas pH and pCO_2 can reveal more subtle dynamics on shorter time scales in the surface ocean (Thomas et al., 2012).

1.3 Coastal and Oceanic systems

The coastal and the oceanic carbonate systems obey the same thermodynamic principles, however, external influences and inputs lead to significant differences between the two. DIC has a residence time of less than a decade in surface waters, from a decade to a century in intermediate waters and up to millennia in deep waters. The natural variability of DIC in each of these waters reflects this stability, meaning that coastal regions and shelf seas undergo natural changes on much shorter time scales compared to the open ocean. The closer proximity of the waters to the atmosphere also means that anthropogenic changes are likely to be greater in the shallow coastal seas than in the deep oceans. This then creates two separate challenges in these two environments: distinguishing large changes in a system with large natural variability and distinguishing very small changes in a system that is very stable.

Furthermore, surface waters in coastal regions tend to be subjected to more varied and direct influences due to their close proximity with the atmosphere and sediment. These influences also experience variability on long and short time scales making a very multi-disciplined approach necessary. On the other hand, studying deep waters brings the inherent problem that we do not know the full range of the natural variability. This problem is then compounded by the fact that at the present time, some of the changes we expect to see are the same size as the error margin of our techniques. These problems highlight the need to a multi-faceted approach to improve our knowledge of the global carbon cycle in both coastal and oceanic areas.

The situation becomes further complicated when taking into account how large scale forcing interacts with local forcing. The North Atlantic Oscillation index is a measure of the pressure differential between Iceland and the Azores, thus giving an indication of the strength of the westerly winds between years. It has been shown that the NAO impacts surface hydrographic properties of the North Atlantic Ocean, which affect the carbonate system through $p\text{CO}_2$ uptake [Belkin, 2004; Lefèvre et al., 2004; Schuster and Watson, 2007; Thomas et al., 2008]. The NAO also exerts a large influence on wind and precipitation patterns across the Northwest Atlantic Ocean [Ionita et al., 2011; Hurrell and Deser, 2009]. Due to the large role that riverine inputs have in the coastal and shelf areas, the NAO can cause significant changes in the coastal regions, as well as in the open oceans [Patsch et al., 2002; Kuhn et al., 2010; Lenhart et al., 2004]. Further imposed on this is the potential change in temperature, stratification and water advection [Hordair and Meijer, 2010; Winther and Johannessen, 2006]. Resolving all of these interactions is inherently difficult as many exert opposing

influence, for example, warmer temperatures increasing the summertime $p\text{CO}_2$, but greater water advection of water with lower DIC, thus decreasing summertime $p\text{CO}_2$. Attempting to quantify each of these roles is fundamental in understanding the variability of the carbonate system in coastal and oceanic systems.

1.3.1 Coastal systems, shelf seas and continental shelves

Despite the relatively small area occupied by continental shelves (7%), these regions support a large amount of marine primary production (15-30%, Gattuso et al., 1998). The potential sink of carbon dioxide that these areas represent makes them significant on a global scale with regards to carbon cycling. The continental shelf can be sub-divided into estuaries and shelf, or marginal, seas and further categorized by latitude band. However, as this thesis only deals with continental shelves in the temperate region, high- and low-latitude continental shelves will not be discussed further.

Cai (2011) defines estuaries as areas between the river mouth and tidewater, where freshwater mixes with seawater. The generally shallow water depth in these areas means that there is close interaction between the sediment, water column and the atmosphere, making estuaries biogeochemically very active. It also means that the water column is relatively easily mixed through wind-forcing and tides. Estuarine regions usually support high levels of biological activity due to the input of nutrients and organic carbon from land, entering the sea either from rivers or runoff. Despite this production estuaries have been defined as overall CO_2 sources, opposed to sinks, supplying $0.25 \text{ Pg C m}^{-2} \text{ y}^{-1}$ (Borges et al., 2005; Cai, 2011). When particularly large concentrations of inorganic nutrients are supplied to these regions, eutrophication can occur, leading to greater heterotrophy than autotrophy. The Northwest European continental shelf saw a large increase in incidences of eutrophication from the 1950's to the 1980's with increasing use of fertilizers and urbanization. Eutrophication has been shown to favor larger phytoplankton species (Grover, 1997) and shifts in community structure have been observed in connection with changing nutrient concentrations (Philippart et al., 2000; Philippart et al., 2007).

Beyond the estuaries, but where the effects of terrestrial input are still felt, are the shelf, or marginal, seas, which can be described as the transition zone between the coast and the open ocean. The Atlantic Ocean has the highest concentration of shelf seas of all the oceans in the world, which include the North Sea, Baltic Sea, Irish Sea, Scotia Sea, and the Mediterranean

Sea. At temperate latitudes the shelf seas show large intra-annual variations in the carbonate system related to the seasonally-driven phytoplankton blooms (Prowe et al., 2009; Ishii et al., 2011; Shadwick et al., 2011; Huertas et al., 2006]. How productive a region is exerts large control over how much carbon is drawn down from the atmosphere. The heterogeneity between continental shelves means that observed air to sea CO₂ fluxes range from 32g C m⁻² a⁻¹ in the East China Sea and the Gulf of Biscay (Tsunogai et al., 1999; Frankignoulle and Borges, 2001) to 17g C m⁻² a⁻¹ in the North Sea (Thomas et al., 2004). The fate of the carbon sequestered in phytoplankton and zooplankton determines whether the overall system acts as a CO₂ source or sink.

In the estuarine/coastal system, it is vital to determine the pathway and fate of the sequestered carbon in order to extrapolate whether regions are overall CO₂ sinks or sources. A shallow water column often means that any CO₂ taken up in biomass is likely to be remineralized and released back to the atmosphere before being transported to the open ocean. The North Sea has been determined an overall CO₂ sink (Bozec et al., 2005) and an example of a *continental shelf pump*, a term coined by Tsunogai, in 1999, who noted the “export” potential of shelf seas with respect to CO₂. It is used to describe the export of carbon drawn down on the shelf and subsequently transported into the deep, adjacent ocean. The northern North Sea performs this operation very effectively, however, the shallower southern North Sea is limited by high remineralization rates in the water column. Contrastingly, shallow regions, and larger classes of phytoplankton, are associated with larger carbon contributions to the sediment (Riegman et al., 1993) where a variable fraction can be remineralized or buried. The higher flux of organic matter to the sediment can also lead to anoxic conditions resulting in the generation of A_T through denitrification or sulfate reduction (Thomas et al., 2009). Such A_T generation could lead to an enhanced buffering capacity of overlying waters, if produced in sufficient quantities, again highlighting the need of a multi-disciplinary approach to carbonate studies in these areas.

1.3.2 Open Ocean

While continental shelves have been shown to hold substantial anthropogenic carbon stores (Lee et al., 2011) they cannot compete with the vastness of the larger oceans. The Atlantic Ocean currently contains ~38% of the total global C_{ant} inventory (Sabine et al., 2004) making it the largest store of all the oceans. In the North Atlantic the deep water formation is largely responsible for the majority of C_{ant} uptake, whereas in the South Atlantic the most effective uptake occurs in the SubAntarctic Zone (McNeil et al., 2007), where large amounts of C_{ant}

are injected into intermediate depths. Despite this efficiency the volume of Antarctic Bottom Water means that this water mass represents one of the most significant stores of C_{ant} in the Southern Ocean (Rios et al., 2012). On a global scale $\sim 50\%$ of C_{ant} accumulation resides in the upper 400 m (Sabine et al., 2004) and this number is predicted to rise as the flux into the ocean accelerates with increasing atmospheric concentrations.

The open ocean generally shows the least variation over short time scales, however, arguably the most over longer time scales. Climatic forcing is one relatively short-term driver, which affects the carbonate system in the surface waters of ocean basins. The NAO index shows strong correlations to temperature and salinity anomalies across the North Atlantic subtropical gyre (Thomas et al., 2008) and to the circulation pattern and inflow rates of the North Sea (Winther and Johannasson, 2006). A shift from a predominantly negative NAO index to predominantly positive index has been suggested as being responsible for a notable decline in $\Delta p\text{CO}_2$ ($p\text{CO}_{2\text{sea}} - p\text{CO}_{2\text{air}}$) observed over the past decade in the North Atlantic Ocean (Lefèvre et al., 2004; Corbiere et al., 2007; Watson et al., 2009). As the effects on the two sides of the North Atlantic subtropical gyre were different, and it takes time for the water to travel, one must consider the immediate effects but also the longer-term lag effects, depending on where and when one is measuring. Such effects have been noted at the European Station for Time series in the Ocean at the Canary Islands (ESTOC) station (Santana-Casiano et al., 2007) and the Bermuda Atlantic Time Series (BATS) station (Bates, 2001) and have also been shown to have an impact on the C_{ant} uptake of the region (Perez et al., 2010).

1.3 Objectives of this thesis

This thesis was designed to build upon an extensive dataset of carbonate system measurements obtained in the North Sea over 5 years, and examine changes in the buffering capacity. Covering the same stations at the same time of year (late summer 2001, 2005 and 2008) allowed direct comparison of the carbonate system and the distribution of carbonate parameters. This work was further complemented with the development of a time-series station adjacent to the North Sea, in the Marsdiep basin of the Wadden Sea, and by continuous $p\text{CO}_2$ measurements on the other side of the North Atlantic basin. Two cruises covering the southwest Atlantic provided further opportunity to examine the processes operating in shelf seas compared to those in the ocean.

1.4 Thesis Outline

This thesis deals with the buffering capacity of coastal and oceanic systems with regard to the continual increase in anthropogenic, atmospheric CO_2 concentrations. The effects of rising CO_2 concentrations are placed in the context of natural carbon variability in a number of environments of the Atlantic Ocean.

In **Chapter 2** we first describe the techniques used to measure the four carbonate variables and assess how robust our basic assumptions of the carbonate system are based on the consistency between the measured and calculated variables. This internal consistency study uses 6 data sets from the North Sea, including four seasonal data sets, to assess how these calculations hold up throughout the year and in different salinity environments within the North Sea. A number of similar studies have been undertaken in the laboratory and in the open ocean, however, here we present the results from the first such study to take place in a coastal or shelf-sea environment.

The Wadden Sea exerts a large influence on the southern North Sea, supplying large quantities of DIC and A_T . In **Chapter 3** we use two and a half years worth of time series data from the Marsdiep basin of the Wadden Sea to examine the seasonal controls on DIC and A_T . This was done in light of recent evidence that coastal sediments could produce significant fluxes of A_T to the overlying waters, facilitating a degree of buffering against increasing CO_2 concentrations. The effects of phytoplankton succession during the spring bloom on DIC and A_T were also investigated.

Having examined the local contributions to the carbon dynamics of the North Sea, placing it in the context of larger scale forcing is also necessary. **Chapter 4** employs three reoccupations of the North Sea during late summer in 2001, 2005 and 2008, during years of differing North Atlantic Oscillation states. We attempt to deconvolute a number of internal and external forcings on the shelf sea to investigate how these conditions control the effectiveness of the North Sea as a ‘shelf pump’ of CO₂.

Time series are often limited by resolution of sampling, thus in **Chapter 5** we use continuous, high-frequency measurements from a CARIOCA buoy coupled with data from a SeaHorse profiler to examine the diel CO₂ cycling occurring on the Scotian shelf throughout the year. We show how temperature and light controls the seasonal, and daily cycle of CO₂ drawdown by phytoplankton.

In **Chapter 6** we examine the increase in anthropogenic carbon, which has taken place over the past 17 years, in the southwest Atlantic Ocean. Here we use the benchmark dataset from the World Ocean Circulation Experiment (WOCE) in 1994 to perform an extended Multi Linear Regression (eMLR) in comparison with the more recent West Atlantic Geotraces section (2010/11). The anthropogenic influx is placed into the context of the buffering capacity of differing water masses. We show that the anthropogenically-driven decrease in pH is not directly proportional to the amount of carbon added to seawater, but relies heavily on other water mass characteristics.

Finally, the main conclusions from this body of research is summarized and placed in the wider context of the field. The implications and recommendations for future research are also discussed.

Chapter 2

The internal consistency of the North Sea carbonate system

Lesley A. Salt, Helmuth Thomas, Yann Bozec, Alberto V. Borges,
and Hein J. W. de Baar.

Abstract

A number of repeat observations of the seawater carbonate system in the North Sea has allowed quantitative assessment of its internal consistency on an inter- and intra-annual scale. In 2002 (February) and 2005 (August) the full suite of carbonate system parameters (Total Alkalinity (A_T), Dissolved Inorganic Carbon (DIC), pH, and partial pressure of CO_2 (pCO_2)) were measured on two re-occupations of the entire North Sea basin, and three parameters (A_T , DIC, pCO_2) measured on an additional four re-occupations in 2001 (August, November), 2002 (May) and 2008 (August), which completed coverage of all four seasons. Here we examine the ability of six different sets of carbonic acid dissociation constants, to accurately and precisely, reproduce measurements taken in a variety of biogeochemical environments. Overall the carbonic acid dissociation constants of Mehrbach et al. (1973), refit by Dickson and Millero (1987), produced the most consistent results, however, in lower salinity environments (salinity < 34.5) those of Mojica-Prieto and Millero (2002) start to outperform those of Mehrbach et al. (1973), refit by Dickson and Millero (1987). For most of the year there is a similar level of internal consistency, with A_T being calculated to within $\pm 6 \mu\text{mol kg}^{-1}$ with DIC and pH, DIC to $\pm 6 \mu\text{mol kg}^{-1}$ with A_T and pH, pH to ± 0.008 with A_T and pCO_2 , and pCO_2 to $\pm 8 \mu\text{atm}$ with DIC and pH. In spring, however, we observe a significant decline in the ability to accurately calculate the carbonate system, with A_T being calculated to $\pm 27.3 \mu\text{mol kg}^{-1}$, DIC to $\pm 23.3 \mu\text{mol kg}^{-1}$, and pCO_2 to $\pm 41.3 \mu\text{atm}$. A significant correlation is present between the internal consistency of DIC and pCO_2 , to the A_T /DIC ratio during this time, which follows a latitudinal pattern, however, the deviations between the calculated and measured A_T values remain constant throughout the basin. There is no clear explanation for this, but we suggest that these patterns are the result of a number of contributing factors, such as, the presence of interfering terrestrial compounds, organic matter and measurement biases.

1 Introduction

Increasing atmospheric carbon dioxide (CO₂) has been partly mitigated by oceanic uptake, which currently accounts for 25-30% of the total CO₂ emissions (Sabine et al., 2004; Canadell et al., 2007). The uptake of CO₂ in surface waters causes a shift in the chemistry of seawater, notably increases in [H⁺] and a decrease in [CO₃²⁻] leading to the phenomenon known as ocean acidification (OA) (Caldeira and Wickett, 2003, 2005; Raven, 2005). Recent findings of Wootton et al. (2008) indicate that ocean acidification is proceeding in coastal areas more rapidly than has been predicted. The associated changes related to OA have been shown to have a variety of effects on marine phytoplankton (Fabry et al., 2008). The coastal zone is responsible for a disproportionately large amount of primary production per surface area as compared to the open ocean (Wollast, 1998) and has been shown to be responsible for a similarly large proportion of carbon export (Dunne et al., 2007). As such, understanding how these waters respond to acidification is vital in accurately predicting the future consequences of continued CO₂ increase.

The North Sea has been identified as an effective continental shelf-pump of CO₂ (Tsunogai et al., 1999; Thomas et al., 2004) and has thus undergone intensive study with respect to the CO₂ system. The high seasonal variability of the carbonate system in the North Sea (Bozec et al., 2006; Prowe et al., 2009) makes the use of high temporally-resolved datasets necessary to understand the observed signals. The use of Voluntary Observing Ships (VOS) to collect underway pCO₂ data have been used extensively in the North Sea (Omar et al., 2010) complemented by measurements of one other of the measurable carbonate variables (total alkalinity (A_T), dissolved inorganic carbon (DIC), and pH). The carbonate system can then be fully solved and quantified using equilibrium equations and constants (Park, 1969) from at least two measured variables (a combination pair of A_T, DIC, pH and pCO₂) that are integrated in computer programs such as CO2SYS (Lewis and Wallace, 1998). These computed parameters are prone to error, which have been well documented (Millero et al., 1993; Lee et al., 2000; Koeve et al., 2011; Hoppe et al., 2012). These errors stem from the accuracy of the two measured variables and to the reliability of the first and second dissociation constants of carbonic acid. The assessment of the reliability of dissociation constants can be achieved with internal consistency studies.

The first internal consistency studies took place in the open ocean and focused on the reliability of the various sets of carbonic acid dissociation constants, which are used to

calculate the distribution of inorganic carbon species. These constants have been determined over a variety of salinities and temperatures, in artificial seawater (Roy et al., 1993; Goyet and Poisson, 1989; Hansson, 1973) and in natural seawater (Mehrbach et al., 1973) and the data were later refitted using improved computer-generated models (Dickson and Millero, 1987). Assessments and comparisons of each set of constants has taken place in several locations, including the equatorial Pacific (Millero et al., 1993) and the North Atlantic (Lee et al., 1997), and spanning across several ocean basins (Wanninkhof et al., 1999; Millero et al., 2002) with little difference in the results. At sea studies have been complemented by further work using laboratory set-ups (Lee et al., 1996; Lueker et al., 2000) and more recently investigations into inconsistencies in culture experiments (Hoppe et al., 2012; Koeve et al., 2011).

The conclusion from these studies is that the pK values of Mehrbach et al. (1973), refit by Dickson and Millero (1987), are the most reliable when calculations involve pCO_2 , that is pCO_2 is being calculated or is being used to calculate another parameter (Wanninkhof et al., 1999; Lee et al., 1996). These constants were the only ones determined in natural seawater and the difference has been attributed to the lack of boric acid in the artificial seawaters. In solution the majority of dissolved boron is present in two forms; boric acid and borate, following the equilibrium relationship below:

In natural seawater boric acid interacts with HCO_3^- and CO_3^{2-} to lower the activity of HCO_3^- and thus pK_2 ($pK = -\log_{10} K$). In contrast, when the computations use pH , A_T , and DIC , the best dissociation constants have been found to be Roy et al., (1993) or Goyet and Poisson (1989) (Lee et al., 1997; Clayton et al. 1995). Despite this, in an attempt to homogenize the way carbon chemists carry out these calculations, it is now the recommended standard procedure to use the constants of Mehrbach et al. (1973), refit by Dickson and Millero (1987), on the Total pH scale (Dickson et al., 2007).

Beyond the scope of dissociation constants, additional errors have been associated with high DIC/A_T ratios (>1.10) (Lee et al., 1996), the interference of fatty acids (Gripenberg, 1960), and contribution from organic acids and bases to A_T (Hernandez-Ayon et al., 2007; Koeve et al., 2011). The latter errors are only thought to be a problem in cultures, where dissolved organic carbon (DOC) reaches particularly high concentrations (Koeve et al., 2011). Similarly, the contributions of fatty acids and high DIC/A_T ratios in the open ocean are so

low that internal consistency remains within the same order of magnitude as the measurement precision. However, in cultures, unaccounted for errors have been much larger, and thus coastal areas where high primary production takes place, could also be susceptible to large errors in calculations of the carbonate system. Furthermore, the recommended constants of Mehrbach et al., (1973) were only determined to salinities above 26. In the coastal ocean it is not uncommon to find salinities falling below this value, which could be introducing further errors in carbonate system calculations. Here we present the first internal consistency study performed in coastal waters with seasonal resolution over a range of salinities and biogeochemical regimes.

2 Methods

2.1 Hydrography

The hydrographic properties in the surface waters of the North Sea demonstrate the presence of 3 different water masses, acknowledged in the literature as North Atlantic water, Baltic water, and German Bight water, with the resulting composite water mass known as Central North Sea Water (Kempe and Pegler, 1991; Bozec et al., 2006). In the northern North Sea, North Atlantic water flows over the Shetland Shelf bringing characteristic warm and high saline waters into the North Sea. In the southeast the Skagerrak water mass, a mixture of Central North Sea water and Baltic water, is easily identifiable through much lower salinities and temperatures than the central North Sea. The German Bight water comes from the Northwest European continental, coastal region in the southern North Sea, where the riverine influence is strongest in the North Sea.

The North Sea can be divided into two biogeochemical regimes, which are dictated in behavior by depth (Thomas et al., 2005; Prowe et al., 2009; Omar et al., 2010). The northern North Sea (nNS)(north of $\sim 56^{\circ}\text{N}$) is deeper than the south (50-400 dbar) and experiences more ocean-like behavior, e.g. higher salinity and seasonal stratification. The southern North Sea (sNS) is much shallower (<50 dbar) and remains well-mixed throughout the year. Both regions receive nutrient and organic carbon inputs from terrestrial sources, facilitating high primary production that leads to overall annual autotrophy in the nNS and near balanced trophic status in the sNS (Bozec et al., 2005; Schiettecatte et al., 2007).

2.2 Measurements and comparisons

The data used in this study comes from 6 separate re-occupations of the North Sea, taking

place in August 2001, November 2001, February 2002, May 2002, August 2005 and August 2008. All four carbonate parameters were measured on two of these cruises; February 2002, and August 2005, with precision of $\pm 2\text{--}3 \mu\text{mol kg}^{-1}$ for A_T , $\pm 1\text{--}2 \mu\text{mol kg}^{-1}$ for DIC, ± 0.001 for pH, and $\pm 1 \mu\text{atm}$ for $p\text{CO}_2$, respectively.

For all of the afore-mentioned cruises, A_T was measured by potentiometric titration to the second end-point (pK_2) of carbonic acid, using 0.1M hydrochloric acid as the titrant. For the cruises taking place in August 2001, November 2001, February 2002, May 2002 and August 2005 the samples for A_T were filtered on GF/F shortly after sampling, prior to analysis. The resultant acid volumes and corresponding e.m.f values are fitted to a Gran titration plot using least squares (Gran, 1952). An uncertainty of $\pm 2\text{--}3 \mu\text{mol kg}^{-1}$ was found for all cruises. The concentrations of silicate and phosphate are required to account for their contribution to A_T , which can be of the order of up to $1 \mu\text{mol kg}^{-1}$ in the North Sea. All of the DIC data collected in the North Sea was analyzed by the coulometric method of Johnson et al. (1993), with an overall uncertainty of $\pm 1\text{--}2 \mu\text{mol kg}^{-1}$ for all cruises. For quality control and calibration of DIC and A_T , Certified Reference Material (CRM), of known DIC and A_T , acquired from Prof. Andrew Dickson (Scripps Institute of Oceanography, USA) were used.

In 2002 and 2005, discrete samples were taken from the CTD and analyzed for pH potentiometrically on the total hydrogen ion scale, calibrated using TRIS (2-amino-2-hydroxymethyl-1,3-propanediol) and AMP (2-aminopyridine) buffers prepared at a salinity of 35 according to Dickson (1993). The accuracy of this method is strongly dependent on the sensitivity of the pH meter and how accurately the two buffer solutions are made up. For the measurements used in this work a precision of ± 0.001 pH units was attained. For all North Sea cruises $p\text{CO}_2$ was measured continuously, underway, from surface waters, providing the greatest coverage of data. The instrument used continuous equilibration with a head-space and infrared detection with an accuracy of $\pm 1 \mu\text{atm}$ (Körtzinger et al., 1996). The calibration of $p\text{CO}_2$ measurements was carried out regularly (every 2-3 hours) using National Oceanic and Atmospheric Administration (NOAA, Global Monitoring Division, Carbon Cycle Greenhouse Gases Group) calibrated gas standards. For all cruises a minimum of 3 calibration gases were used, spanning a concentration range from 0 ppm to 750 ppm.

2.3 Calculations

The internal consistency was assessed using the measured in-situ salinity, temperature, and

pressure values. The KSO_4 constants of Dickson (1990) were used and pH values are given throughout on the total hydrogen ion scale. Not all station positions were occupied and measured in all six cruises that are compared here. In order to overcome this the percentage of data points considered internally consistent is often used to allow direct comparison without the loss of data. The calculations were performed using the CO2_SYS program (Lewis and Wallace, 1998), adapted for MATLAB (van Heuven, 2009). All calculated parameters as a function of two input parameters were explored, thus consisting of: $A_T(\text{DIC}, \text{pH})$, $A_T(\text{DIC}, \text{pCO}_2)$, $A_T(\text{pH}, \text{pCO}_2)$, $\text{DIC}(A_T, \text{pH})$, $\text{DIC}(A_T, \text{pCO}_2)$, $\text{DIC}(\text{pH}, \text{pCO}_2)$, $\text{pH}(\text{DIC}, A_T)$, $\text{pH}(\text{DIC}, \text{pCO}_2)$, $\text{pH}(A_T, \text{pCO}_2)$, $\text{pCO}_2(\text{DIC}, A_T)$, $\text{pCO}_2(\text{DIC}, \text{pH})$, and $\text{pCO}_2(A_T, \text{pH})$, for the following six different sets of carbonic acid dissociation constants: Roy et al. (1993)(ROY), Goyet and Poisson (1989)(GP), Hansson (1973), refit by Dickson and Millero (1987)(HAN), Mehrbach et al. (1973), refit by Dickson and Millero (1987)(MEH), Hansson and Mehrbach, refitted by Dickson and Millero (1987)(HM) and Mojico-Prieto and Millero (2002)(MM). In the remaining text, for simplicity, the constants will be referred to by the abbreviations (ROY, GP, HAN, MEH, HM and MM).

2.4 Assessment

The internal consistency of the carbonate system can be considered in a number of different ways. Here, we assess how accurate and precise it is by comparing measured parameters to calculated parameters. An accurate but imprecise system would be indicated by a low average (absolute) difference between the measured and calculated values, but with a high standard deviation (noise) around this average. A precise but inaccurate system, however, is indicated by a low standard deviation of differences, between calculated and measured parameters, but with a high average difference. Alternatively, the system can be accurate and precise, resulting in a small average difference between the measured and calculated values, accompanied by a low standard deviation of differences. The measured and calculated values of each parameter, for each set of dissociation constants, was fitted to the form $Y = a.X$, by means of linear regression, the results are shown in Table 1.

2.5 Error Propagation

When the term ‘internally consistent’ is used, it refers to whether the calculated values and associated errors fit within the limits of the errors propagated through the calculations from the initial measurements. Measurement errors are carried through in the calculations and depending on the input parameter combination lead to different error margins in the resultant

values. These margins vary insignificantly over the range of conditions (e.g. temperature, salinity) observed in the North Sea, thus average margins were calculated using basin-wide average temperature, salinity, silicate and phosphate concentrations. The carbonate parameters were set to minimum or maximum values (average measured values \pm error) to obtain the largest error margin possible. This carried through calculation error (CE) was then divided by two to create an error margin on both sides, which then had the respective measurement error (ME) of the calculated parameter added on. The variation in CE for different carbonic acid dissociation constants is less than 0.5% of the parameter, thus the same CE was applied for all the dissociation constants.

2.6 Total Borate Calculations

To independently calculate the total borate contribution from each water mass, the individual water mass fractions were first calculated, following Friis et al. (2005). The German Bight constitutes a complex mixture of different water masses, with input from several rivers, thus distinguishing an end member is impossible. Instead, for our purposes, we used the salinity and A_T data from the station closest to the German Bight to form a regression line with the Central North Sea end member. We then extrapolated this down to a salinity of 0 to get a representative freshwater end member. This assumes that all the fresh water present comes from the same source, however, due to other rivers in the region having a similar catchment lithology we assume that the chemical signal of the water will be similar. Comparing the regressed value with recent seasonal A_T data from the Elbe (Thorben Amann, *pers. comm.*) we find end member values in the same range as that calculated here, thus we assume our estimation is sufficient for the purpose of the calculation.

The borate alkalinity (BAlk) was then calculated for the end members, using the equations of Barth (1998) (equations 8 and 9) for the salinity-borate relationship in the German Bight, and that modified from Gripenberg (1960) (equations 10 and 11) for the Baltic salinity-borate relationship. At a salinity of 35 the two seasonal linear relationships of Barth (1998), for summer (September, 1994) and winter (February, 1995), yield an average difference of 50 $\mu\text{mol kg}^{-1}$ in the calculated borate. As such, for our calculations, equation 8 was used for the calculations of August 2005 (summer), and equation 9 for the calculation of February 2002 (winter). The water mass fractions were then multiplied by the theoretical BAlk contribution and summed to obtain the actual BAlk of the sample.

$$B = 0.13 \cdot S + 0.18 \text{ (for sept, 1994)} \quad \text{(equation 8)}$$

$$B = 0.14*S + 0.17 \text{ (for feb, 1995)} \quad (\text{equation 9})$$

The salinity-borate relationship in the Baltic is less well documented, however, the following equation was regressed from the data presented by Grippenbergs (1960):

$$B = 14.0111*S - 3.3103 \quad (\text{equation 10})$$

with an R^2 value of 0.9, where B represents boric acid measured in meq kg^{-1} and salinity has been converted from chlorinity using Lewis (1980, $S = 1.80655 \text{ Cl}\%$). The data of Grippenbergs (1960) was obtained mainly in the Baltic proper and into the Bothnian Sea, the latter of which, Beldowski et al. (2010) show, has a much steeper salinity-alkalinity relationship than the Baltic Proper. Borate demonstrates conservative behavior, similar to alkalinity, thus we assume a constant relationship between alkalinity and borate throughout the Baltic. We can then use the ratio of B/A_T from the data of Grippenbergs, adapted to the regression of Beldowski et al. (2010), for the Baltic proper, to form an equation between borate and salinity. The resulting equation for the total boron in the Baltic is:

$$B = 1.8848*S + 95.741 \quad (\text{equation 11})$$

where B represents total boron in $\mu\text{mol kg}^{-1}$.

For the North Atlantic fraction the traditional seawater relationship of Uppstrom (1974) was used:

$$B = (0.000232/10.811)*(S/1.80655) \quad (\text{equation 12})$$

3 Results and Discussion

3.1 A seasonal comparison

The two seasons with data from four measured carbonate parameters are winter (February) and summer (August), allowing us to compare the internal consistency in two very different conditions in terms of values of the carbonate variables, and water temperature. As the North Sea is a temperate coastal sea, it is characterized by high primary production during summer and very low, or no, production in winter. The average DIC in February 2002 was $64 \mu\text{mol kg}^{-1}$ higher than that in August. The average A_T changed by just $2 \mu\text{mol kg}^{-1}$, however, the various contributions to A_T showed greater variability. We calculated the different A_T contributions in the North Sea in February 2002 and August 2005 (Figures 1a and 1b). For

average annual conditions in the North Sea, the HCO_3^- and CO_3^{2-} species are by far the greatest contributors to A_T , supplying $\sim 2212 \mu\text{mol kg}^{-1}$, followed by borate (B(OH)_4^-) ($\sim 68 \mu\text{mol kg}^{-1}$), hydroxide (OH^-) ($\sim 3 \mu\text{mol kg}^{-1}$), phosphate (PO_4^{3-}) ($\sim 0.07 \mu\text{mol kg}^{-1}$) and silicate (SiO(OH)_3^-) ($\sim 0.04 \mu\text{mol kg}^{-1}$). The largest change between the two seasons was in carbonate alkalinity ($\text{HCO}_3^- + 2\text{CO}_3^{2-}$), which was significantly lower in August, when photosynthesis occurred. The contributions of silicate and phosphate were also much smaller then, due to uptake by phytoplankton. The borate contribution was slightly higher in August, which is mainly the effect of temperature on K_B .

The change in average $p\text{CO}_2$ was just $8 \mu\text{atm}$, however, this is not representative of the entire North Sea, as the $p\text{CO}_2$ range is two times greater in August ($287 - 455 \mu\text{atm}$) compared to February ($315 - 396 \mu\text{atm}$). The greater range in summer reflects the two biogeochemical regimes within the North Sea: the stratified nNS, where stratification enables prolonged phytoplankton growth causing a large drawdown of CO_2 , shows very low $p\text{CO}_2$ values, whereas in the sNS, very low $p\text{CO}_2$ values are observed only in spring and a combination of remineralization and higher temperatures lead to much higher $p\text{CO}_2$ in August (Bozec et al., 2005; Thomas et al., 2004, 2005; Schiettecatte et al., 2007). In February, the water column is well-mixed throughout, and biological activity is lower thus leading to a more homogenous horizontal distribution of $p\text{CO}_2$.

The results from all internal consistency calculations using the 4 carbonate parameters, with various dissociation constants, in the February 2002 and August 2005 data sets are shown in Tables 1 and 2, respectively. The regressed data fitted the calculated values to measured values (measured value on the y-axis and calculated value on the x-axis), thus a regression with a slope >1 indicates that the measured value is greater than the calculated value. A regression slope of 1.000 is achieved with several combinations in both seasons; 6 times in winter and 3 times in summer. In February, when the parameters involved are DIC, A_T and $p\text{CO}_2$, we find that the constants of MEH are the most suitable, whereas when DIC, A_T and pH are involved the constants of GP outperform the others. The largest deviations and residuals are consistently observed when the input parameters are pH and $p\text{CO}_2$, with MM producing the most accurate reproduction of measurements. In August the constants of MEH are, again, the best choice when the parameter combination is A_T , DIC and $p\text{CO}_2$ but also when A_T , DIC and pH are all involved. However, for calculations involving pH and $p\text{CO}_2$ the constants of GP or HAN are most appropriate.

In general the difference in precision (represented by the standard deviation) between the dissociation constants was minor compared to the differences obtained with various input parameter combinations. The results for both February and August are consistent, showing that the best calculation combination for A_T was (DIC,pH), for DIC it was (A_T ,pH), for pH it was (A_T ,pCO₂) and for pCO₂ it was (DIC,pH). The results from February show a slight decrease in precision, represented by a higher standard deviation, compared to that obtained in August, however, the regressions indicate a lower accuracy. The standard deviations of the differences between the calculated and measured parameters (Δ) for February 2002 and August 2005 (shown in brackets, respectively) are approximately double to those found in the open ocean by Lee et al. (1997), of $\pm 3 \mu\text{mol kg}^{-1}$ in A_T ($\pm 6, 7 \mu\text{mol kg}^{-1}$), $\pm 3 \mu\text{mol kg}^{-1}$ in DIC ($\pm 6, 7 \mu\text{mol kg}^{-1}$), and $\pm 1.3\%$ of pCO₂ ($\pm 3, 2\%$).

3.1.1 The effects of salinity on dissociation constants

Different salinity and temperature parameterizations used in the determination of pK₁ and pK₂ are largely responsible for the deviations in the calculations between dissociation constants. Plotting the difference in ΔA_T ($A_{T,\text{meas}} - A_{T,\text{calc}}$), ΔDIC , ΔpH and ΔpCO_2 between results from different dissociation constants shows an exponential increase around a salinity of ~ 34.5 , indicating that at higher salinities the choice of dissociation constants becomes more significant. To investigate the performance of the six dissociation constants at different salinities, the North Sea data from August and February were split into two groups; low salinity waters, with salinities less than 34.5, and high salinity waters, with salinities greater than or equal to 34.5. The same linear regressions were then applied again to the two different groups. The 1 standard deviation (sd) of ΔA_T , ΔDIC , ΔpH and ΔpCO_2 is greater, for all parameters and in both seasons, for low salinity waters compared to high salinity waters. In high salinity waters in February the sd of ΔA_T decreases by $2 \mu\text{mol kg}^{-1}$, DIC by $1 \mu\text{mol kg}^{-1}$, pH by 0.002 and pCO₂ by $2 \mu\text{atm}$. In the less saline waters, there is an increase in the sd of ΔA_T , ΔDIC , ΔpH and ΔpCO_2 by $2 \mu\text{mol kg}^{-1}$, $1 \mu\text{mol kg}^{-1}$, 0.003, and $2 \mu\text{atm}$, respectively. The same pattern is observed in August, however, the differences are smaller, with the sd of ΔA_T decreasing by $1 \mu\text{mol kg}^{-1}$, DIC by $1 \mu\text{mol kg}^{-1}$, pH by 0.002 and pCO₂ by $1 \mu\text{atm}$ in high salinity waters, and increasing the sd of A_T by $<1 \mu\text{mol kg}^{-1}$, DIC by $<1 \mu\text{mol kg}^{-1}$, pH by 0.001 and pCO₂ by $2 \mu\text{atm}$ in low salinity waters.

Furthermore, in February, a clear separation appears between the different dissociation constants in low and high salinity waters. As previously mentioned, over the total dataset, when DIC, A_T and pH are involved in calculations, the constants of GP produce the least

deviation between measured and calculated parameters, however, in high salinity waters the constants of MEH become more appropriate and in the lower salinity waters the constants of ROY outperform the others. Despite these changes, the constants of MM show little variation in performance between the two salinity environments. For August there was no difference between the most suitable constants for the entire dataset compared to the different salinity regimes regarding measurements with DIC, A_T and pH, with GP still most closely representing the measurements. With regard to measurements of pH, pCO_2 and DIC, however, in the lower salinity waters the constants of HAN outperformed those of GP. Similarly to February, the constants of MM also perform well and show the best consistency across the entire salinity range.

At lower salinities the ratio of K_1/K_2 is greater [Mosley et al. 2010; Zeebe and Wolf-Gladrow, 2001] leading to relatively greater HCO_3^- concentrations compared to CO_2 and CO_3^{2-} . This ratio is used directly in the calculation of pH and A_T from DIC and pCO_2 . Due to the different parameterizations of K_1 and K_2 for the different constants, the difference in this ratio between constants may become larger or smaller at lower salinities. This will lead to greater or smaller differences between the measured and calculated parameters. As such, at lower salinities, one would expect, overall, greater variation between the calculations from the different dissociation constants, as is observed here. The salinity range does not change between the two seasons, however, in February, 2002 a 3.5 fold higher Elbe river discharge was recorded compared to August, 2005 (GKSS, 2012, <http://coast.gkss.de/staff/kappenberg/elbe/abfluss/elbe.abfluss>). A greater proportion of freshwater in the North Sea could explain why a greater difference is observed between the two salinity environments during this time. Based on these results, for datasets that cover a large range of salinities, for consistency, one can achieve the best overall results using the constants of MM in carbonate system calculations.

3.1.2 The Role of Borate Alkalinity

The ratio of K_1/K_2 varies between parameterizations of dissociation constants partly, depending on whether the constants were determined in artificial seawater or natural seawater. In natural seawater interactions between borate and carbonate cause a decrease in K_1 and an increase in K_2 (Prieto & Millero, 2002), which does not occur in artificial seawater due to the lack of boron. Thus, the fact that the constants of ROY and MM outperform those of MEH in less saline waters may be indicative of their lower borate concentration, thus the difference in pK_2 is not as large as in more saline waters. Borate has a long residence time in

the oceans leading to a conservative relationship with salinity, thus in carbonate system calculations the total boron contribution is calculated as a linear function of salinity, and the borate then calculated using K_B . In the North Sea, the Baltic input through the Skagerrak, and the Elbe input in the German Bight, have demonstrated non-conventional salinity-borate relationships (Barth, 1998). Figure 1 shows clearly that borate is the second largest non-carbon contributor to A_T , constituting ~4% (Zeebe and Wolf-Gladrow, 2001), thus deviations from the true borate concentration can potentially cause substantial errors in calculations involving A_T . Furthermore, the K_B of the boric acid system is very close to ocean pH, thus any miscalculation of $[H^+]$ can also lead to significant errors in the calculation of $[B(OH)_3]$ and $[B(OH)_4^-]$ concentrations.

To evaluate the potential error introduced into calculations of the carbonate system in the North Sea by unaccounted-for borate, the borate concentrations in the Elbe- and Baltic-influenced areas of the North Sea were calculated using the water mass fractions and borate-salinity equations from the literature (see section 2.5). This ‘pre-calculated’ borate contribution to alkalinity ($Balk_{pre}$) was then implemented into CO2_SYS, replacing the salinity-borate calculation (Uppstrom et al., 1974), which the program normally uses. For comparative purposes $Balk$ was also calculated using the traditional equation (Uppstrom et al., 1974) with various $[H^+]$ determinations, including that from direct pH measurements, using DIC and A_T as inputs and using A_T and pCO_2 as inputs (DIC/ pCO_2 produce the same results as A_T/pCO_2 , hence have not been included). We found that the $Balk_{pre}$ calculations showed little change from the $Balk$ concentrations, the difference showing a normal distribution with 0 as the absolute mean and 2σ of $8 \mu mol kg^{-1}$. The equations of Barth (1998) are very similar to the oceanic relationships, thus no significant difference was observed in the German Bight between the two calculations. The greatest difference occurs in the Skagerrak where CO2_SYS over-estimates the $Balk$ compared to the equation derived from Gripenberg’s data. This was particularly so in August 2005, when the Uppstrom et al. (1974) ratio overestimated the $Balk$ contribution by up to $8 \mu mol kg^{-1}$. Despite these differences, using our derived $Balk_{pre}$ values did not improve the internal consistency. In fact it led to greater deviations between the measured and calculated parameters, reducing the number of internally consistent stations for all input combinations. We thus conclude that the non-conservative salinity-borate relationships in the North Sea are not significant contributors to the lack of internal consistency.

For our second ‘experiment’, the $[H^+]$ concentration from pH measurements was used to calculate $Balk$ directly, and this value is implemented in CO2SYS, however, again this

resulted in a reduction in internal consistency. On the other hand, when the BAlk calculated using $[H^+]$ from (DIC, A_T) is implemented the internal consistency improves notably if DIC or A_T are being calculated, for both February and August. The number of internally consistent (IC) stations in February and August, for A_T (DIC,pH) and DIC(A_T ,pH), increased by 7 and 29 stations respectively, which represent a respective 11% and 36% increase in internal consistency. The internal consistency of A_T (DIC,pCO₂) increased by 5 (8%) and 15 (19%) stations for February and August, respectively, and DIC(A_T ,pCO₂) increased by 4 (6%) and 13 (16%) stations, respectively. It should be noted that the $[H^+]$ calculated from (DIC, A_T) is only used to calculate the BAlk, whereas the $[H^+]$ used in the other calculations is calculated from the stated input parameters. These results indicate that it is the effect of miscalculation of $[H^+]$ on the BAlk concentration that contributes to the lack of internal consistency for (A_T , pCO₂) and (DIC, pCO₂). This can be illustrated by Figure 2, where the change in ΔA_T between the measured and calculated values are plotted against the change in BAlk between that calculated from (DIC, A_T) and (DIC, pCO₂). When the BAlk from (DIC, A_T) is implemented the ΔA_T values are shifted towards the x-axis (0), indicative of the improvement in internal consistency. The reason for such a bias is unknown, and may be caused by an undetected bias in one of the measured parameters.

Of the observed increases in internal consistency, the Skagerrak region shows no change with the new BAlk concentrations. Using the additional seasonal datasets, the largest fraction of Baltic water found in the Skagerrak is present in May (17%), during which time there is a significant ($R^2=0.55$, $p=0.008$) positive correlation between the Baltic fraction and the deviation between calculated and measured parameters (Figure 2(b)). Despite this, in May, the internal consistency could also not be improved by changing the BAlk calculation. Gripenberg (1960) concluded, from back titrations of alkalinity, that whilst borate did not directly affect the accuracy of the A_T titrations, the interactions between boric acid and organic material could lead to underestimated alkalinity values. Thus in May, the lack of internal consistency could stem from some interaction between boric acid and the additional organic material in the water at this time of year. This would lead to unpredictable and random variations in the total alkalinity, however, there would be no pattern to the lack of internal consistency and no way to correct for such an effect.

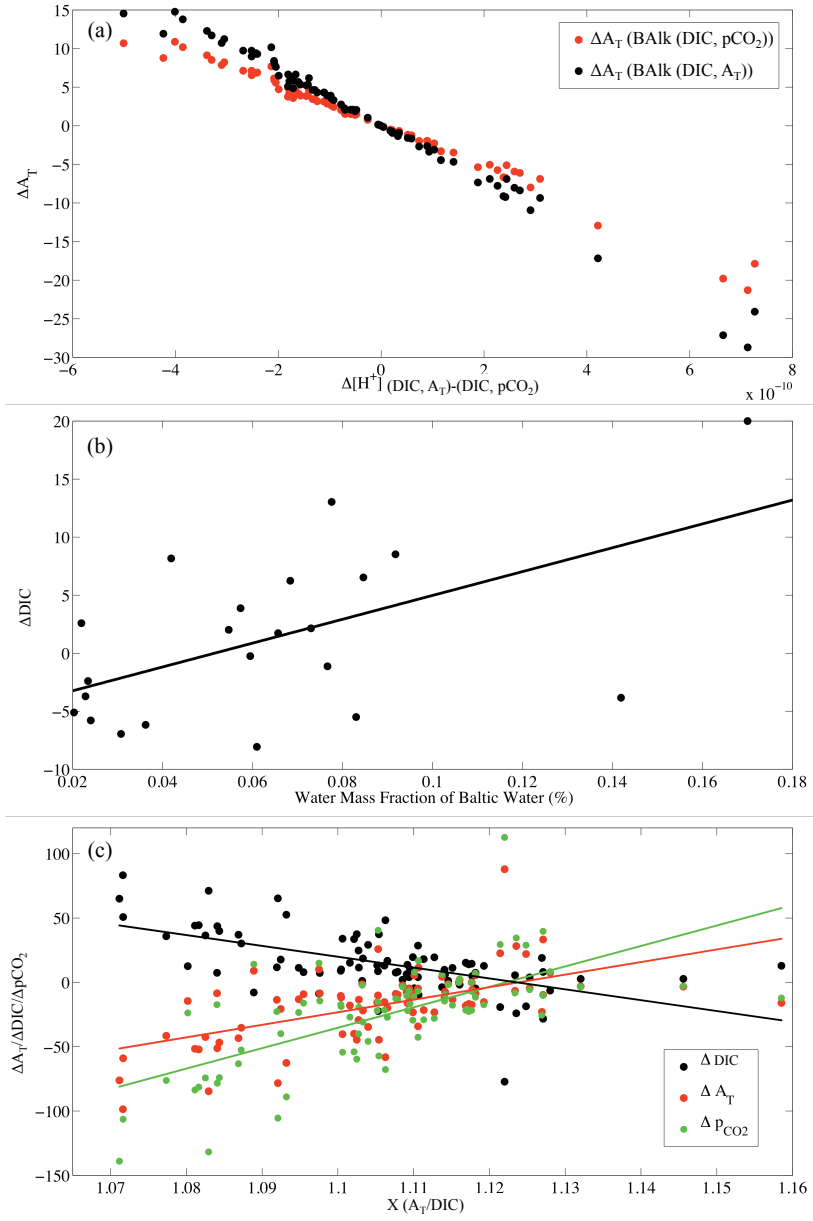

Figure 2. (a) The change in ΔA_T caused by the difference in $[H^+]$ calculated using (DIC, A_T) and (DIC, pCO_2). (b) Regression of ΔDIC with the calculated water mass fraction of Baltic water, selectively displaying those with a fraction of 2% or higher. (c) The change in ΔDIC , ΔA_T , and ΔpCO_2 observed with a varying ratio of A_T/DIC (X).

3.2 Seasonal comparison (A_T , DIC, and pCO_2)

3.2.1 Seasonal Internal Consistency

The results from the internal consistency study from all 6 data sets, using just three carbonate parameters (A_T , DIC and pCO_2) show a clear dominance of the constants of MEH outperforming the others. The results of the seasonal calculations with the use of MEH constants are given in Table 3. These statistics indicate that the internal consistency of the North Sea follows a slightly seasonal pattern, with May - the most biologically productive time period - producing the most inconsistent calculations and the rest of the year displaying a very similar level of consistency. These findings are in agreement with those of Koeve et al. (2011) and Hoppe et al. (2012), whom have similarly noted significant inconsistencies in the carbonate system in waters of high biological activity.

Table 3. Derived linear regressions (regress) and standard deviations (stdv) of differences between measured and calculated parameters with the percentage of internally consistent stations (IC) for all six cruises. The calculations were performed using the acid dissociation constants of Mehrbach et al., (1973), refit by Dickson and Millero, (1987).

As the North Sea consists of two different biogeochemical regimes, the northern North Sea (nNS) and the southern North Sea (sNS), we investigated whether these two environments contributed towards a difference in the internal consistency of the carbonate system. The North Sea was subsequently divided along the 56°N latitude and the internal consistency re-examined in both areas (Table 4). In May there is a significant increase in the standard deviation of ΔDIC and ΔpCO_2 in the north compared to the south, however, ΔA_T shows no difference. It is in the nNS that larger phytoplankton blooms are maintained for long periods due to seasonal, thermal stratification in contrast to the sNS where rapid remineralization takes place in the permanently well-mixed water column. As previously mentioned there is also greater freshwater influence in the sNS however, the difference observed between the north and south is greater than the difference previously mentioned between oceanic and estuarine waters. Errors have previously been associated with intense biological activity (Hoppe et al., 2012), thus we are inclined to suggest that this may have a similar effect here, however, it is interesting that the errors in ΔA_T are not affected on a latitudinal gradient, as ΔpCO_2 and ΔDIC are.

The different regimes also influence the dominant phytoplankton species present in each location. Calcifying organisms and coccolithophore blooms are well documented in the nNS where their growth is controlled by North Atlantic influence and the stratification of the water column (Houghton et al., 1991; Burkill et al., 2002). These organisms influence the A_T/DIC (X) ratio of the waters through calcification which removes one mole of DIC per 2 moles of A_T . Lee et al. (1996, 1997) found that high X (>1.10) values have an impact on the sensitivity of pK_2 , thus affecting the consistency between measured and calculated carbonate parameters. The range of X found in the North Sea varies from 1.06 - 1.16 throughout the year with largest range (1.07 - 1.16) found in May. During this season X also shows a positive linear correlation with ΔDIC , ΔA_T and ΔpCO_2 with R^2 values of -0.6, 0.6 and 0.7, respectively (Figure 2 (c)). The size of the error introduced by varying X can be up to 5 $\mu\text{mol kg}^{-1}$, as found by Lee et al. (1996), which would contribute a large proportion of the errors we observe. In the North Sea, the presence of coccolithophores may also contribute to errors in DIC measurements if in the sample, while A_T samples were filtered. As the method relies on the acidification of the sample, the added acid may conceivably dissolve any CaCO_3 present, introducing noise into the method (Dickson et al., 2007).

The range of X does not impact the errors in A_T , which remain elevated throughout the basin. The A_T is altered by the uptake and release of NO_3^- and NH_4^+ during photosynthesis (Brewer and Goldman, 1976), contributing up to 33 $\mu\text{mol kg}^{-1}$ to A_T in some regions (Wolf-Gladrow

Table 4. Calculated internal consistency statistics for each data set divided into northern North Sea stations (nNS)(latitude>56°N) and southern North Sea stations (sNS)(latitude≤56°N). The calculations were performed using the acid dissociation constants of Mehrbach et al., (1973), refit by Dickson and Millero, (1987).

et al., 2008; Hydes et al., 2012). Fraga & Alvarez-Salgado (2005) quantified the change in A_T during photosynthesis and found that the differences are caused predominantly by N_2 fixation, DMSP production and $CaCO_3$ formation, of which the latter contributes the greatest. Samples were filtered before A_T analysis, thus eliminating the possibility of an error being introduced if some of the $CaCO_3$ shell is dissolved during the A_T titration. Furthermore, in other studies (Hoppe et al., 2012) where samples were filtered for A_T , this did not result in improved internal consistency, suggesting that dissolution of $CaCO_3$ during the titration may not be a dominant factor in deviations between the measured and calculated carbonate parameters.

The North Sea receives a high input of allochthonous dissolved organic matter, for which analysis of colored dissolved organic matter (CDOM) indicates a large proportion is of terrigenous sources (Stedmon et al., 2009) and thus may contain terrestrial “titratable” compounds not accounted for in our analysis. It has been suggested that fatty acids may contribute to measured A_T and in the Baltic Sea there is a higher than average concentration of fatty acids. The contribution of these to A_T has been fairly extensively examined by Osterroht (1993) and maximum contributions of 5 nM A_T were found, which is insufficient to cause the inconsistencies observed here. Muller et al. (2008), using the technique of Hernandez-Ayon et al. (2005) on fjord surface waters, compared the A_T estimation of DIC to the measured value and found that organic alkalinity can contribute from 2-22 $\mu\text{mol kg}^{-1}$ in regions of high organic matter. This could account for the differences observed here in May, however, an additional alkalinity component not accounted for would lead to a larger measured A_T values not lower. As such any organic compound would not be contributing to A_T but detracting from it. As such, it is likely a number of factors contributing to the observed pattern.

4 Conclusions

On a basin-wide scale in the North Sea we find that the dissociation constants of carbonic acid of Mehrbach et al. (1973), refit by Dickson and Millero, (1987), provide the best internal consistency in agreement with previous findings (Lee et al., 1996; Wanninkhof et al., 1999). In regions of lower than average ocean salinity (34.5), there is markedly less deviation between the internal consistency of the different constants and the constants of MM outperform those of MEH. At high salinities these two sets of constants are comparable in performance, thus over datasets with a wide variety of salinities, we recommend the use of MM constants for more consistent calculations.

In the North Sea in general we find that the internal consistency of the carbonate system is much less than that found in the open ocean, by approximately 2-fold, which is unsurprising considering the additional input of terrestrial compounds in coastal areas, and generally higher biological productivity. The internal consistency is relatively constant throughout the year, with the exception of May, where there is a marked decrease in our ability to accurately calculate the carbonate system. This is consistent with previous findings of reduced internal consistency in the presence of high biological activity. A significant correlation with X (A_T/DIC) is found during this period, which is likely to contribute to the errors observed. Calcification, calcifying organisms, changes to A_T due to photosynthesis may all also be a contributing factor to noise during this time of year, however, no definitive conclusions can be drawn here.

Chapter 3

Seasonal carbon dynamics in the Marsdiep basin of the Wadden Sea

Lesley A. Salt, Helmuth Thomas, Astrid Hoogstraten, Katja Phillippart,
Josje Snoek, and Hein J. W. de Baar.

Abstract

Seasonal and inter-annual variations of dissolved inorganic carbon (DIC) and total alkalinity (A_T) are analyzed for a 30-month time series station in the Marsdiep basin of the Wadden Sea. Undersaturation of the surface water partial pressure of CO_2 (pCO_2), relative to the atmosphere, occurs at the time of the spring diatom bloom causing a significant CO_2 drawdown. The diatom bloom had a calculated NCP of $0.95 \text{ mol C m}^{-2}$ in 2009, and $1.24 \text{ mol C m}^{-2}$ in 2010. The difference in NCP between the two years is attributed to a higher wintertime silicate concentration in 2010. The DIC continues to decrease after the diatom bloom, with the successive *Phaeocystis globosa* bloom, however, a combination of pelagic remineralization and increasing temperature increases the pCO_2 in the Marsdiep above that of the atmosphere. The DIC signal shows the same seasonal pattern as that in the adjacent southern North Sea (sNS), indicative of similar controls. In contrast the A_T signal demonstrates inverse seasonality compared to that of the adjacent sNS, which we attribute to the substantial impact of ongoing redox reactions related to the nitrogen cycle. The decline in A_T observed from spring to summer is likely to be caused by a combination of nitrification and ammonia uptake, however, rapid remineralization and recycling of nitrate and ammonia make quantification of each process problematic. From autumn through to winter A_T can be well constrained from DIC concentrations, with the ratio between the two strongly indicative of a dominance of denitrification driving the remineralization process.

1 Introduction

The coastal zone is an important biogeochemical pathway of carbon from land to sea, delivering up to 32 T mol (1 T mol = 10^{12} mol) of dissolved inorganic carbon (DIC) and 20.5 T mol of dissolved organic carbon (DOC) every year (Maybeck, 1982, 1993). The concomitant supply of inorganic nutrients stimulates a large amount of primary production, meaning that coastal regions facilitate up to 30% of total oceanic primary production (Wollast, 1991; Gattuso et al., 1998). In temperate regions, large intra- and inter-annual variability leads to large fluxes of CO_2 between the ocean and atmosphere (Thomas et al., 2004; Chen and Borges, 2009; Gypens et al., 2011; Shadwick et al., 2011) making these regions significant to the global carbon budget. In an extensive literature survey by Borges et al. (2005), coastal seas have overall been classified as CO_2 *sinks*, and estuaries as *sources*. It has been calculated that continental shelves represent a CO_2 sink of $-0.25 \text{ Pg C m}^{-2} \text{ y}^{-1}$ whereas estuaries act as a source of $+0.25 \text{ Pg C m}^{-2} \text{ y}^{-1}$ (Cai, 2011). Despite this broad generalization there is great heterogeneity between coastal systems, with differences in CO_2 uptake ranging from $32 \text{ g C m}^{-2} \text{ a}^{-1}$ in the Gulf of Biscay (Frankignoulle and Borges, 2001) to $17 \text{ g C m}^{-2} \text{ a}^{-1}$ in the North Sea (Thomas et al., 2004), thus highlighting the need to study coastal and estuarine systems on an individual basis.

The North Sea is an effective shelf pump of CO_2 (Thomas et al., 2004), which is significantly influenced by the numerous coastal systems, which border it. The Wadden Sea is a shallow system of tidal flats, located off the coast of the Netherlands and Germany, and delivers approximately $62 \times 10^9 \text{ Gmol y}^{-1}$ DIC (Brasse et al., 1999), and circa 73 Gmol y^{-1} of A_T (Thomas et al., 2009) to the German Bight, in the southern North Sea (SNS). In the shallow Wadden Sea, where depth ranges from 2-3m, it has been estimated that 48% of the organic matter is turned over in the sediment compared to just 10% in the German Bight (van Beusekom et al., 1999). Benthic remineralization thus has a much larger impact on carbon metabolism in the Wadden Sea compared to that on the shelf or in the open ocean, making it just as important as pelagic remineralization (Heip et al., 1995). Benthic remineralization of organic matter quickly depletes oxygen in the sediment, following which, nitrate (NO_3^-), manganese oxide (MnO_2), iron oxide (FeOOH), and sulfate (SO_4^{2-}) are used as electron acceptors, in that order (Richards et al., 1965). The increasing anoxic conditions thus stimulate the release of dissolved Mn, Fe, PO_4^{3-} and H_2S through reduction, as has been observed in the Marsdiep basin of the Wadden Sea (Schoemann et al., 1998; Kowalski et al., 2011). Due to the seasonal biological production in the Marsdiep, the sediment also undergoes a yearly cycle of redox reactions (Schoemann et al., 1998), largely dependent

upon the oxygen penetration into the sediment. The extent of exchange, of the reactants and products of these reactions, between the sediment and water column relies largely upon the type of sediment and the hydrography (Beck and Brumsack, 2012).

In coastal environments the nitrogen cycle is closely linked to the carbon cycle (Fennel, 2010; Pätsch and Kühn, 2008), particularly through riverine contributions (Hofman et al., 2009). It has been observed that in shelf environments the generation of total alkalinity (A_T) from calcium carbonate dissolution is significantly less than that generated from other shelf processes (Chen, 2002). Via a number of redox reactions in the nitrogen cycle, such as denitrification, nitrification and through the assimilation of nitrogen species by phytoplankton or bacteria, a significant amount of total alkalinity (A_T) can be generated or removed (Chen and Wang, 1999; Wolf-Gladrow et al., 2007; Thomas et al., 2009). Nitrogen species thus have an indirect influence on pH in riverine and estuarine systems (Hofmann et al., 2009). In the southern North Sea a maximum in benthic denitrification has been identified near the mouths of the rivers Rhine and Elbe (Proctor et al., 2003) and it has been calculated that a combination of sulfate reduction and denitrification in sediments of the SNS could facilitate 20-25% of the CO_2 uptake in the North Sea (Thomas et al., 2009) making these processes significant to the marine carbonate system.

The European riverine supply of nitrogen to the coastal zone increased notably from the 1950's onwards but has shown a decline since the 1980's (Loebl et al., 2009 (and more references herein); Borges and Gypens, 2010). Terrestrial loading of nutrients can lead to a greater increase in heterotrophy than in autotrophy (Cai, 2011), and has also been shown to influence the community structure of the present phytoplankton species (Bakker et al., 1994; Philippart et al., 2000; Philippart et al., 2007). Eutrophication favors large-celled phytoplankton species (Grover, 1997), which are associated with greater fluxes to the sediment than small-celled organisms (Riegman et al., 1993). One species that can compete with the larger cells is the Haptophyte *Phaeocystis*, which forms large colonies resistant to zooplankton grazing. An increase in *Phaeocystis globosa* abundance was observed in the Marsdiep during the 1970's, associated with eutrophication (Cadée and Hegeman, 2002). As such, changes in riverine flows or loads of inorganic nutrients can have a significant impact on coastal primary production and carbon metabolism (Cadée, 1992; Loebl et al., 2009).

The main objective of the present paper is to investigate the seasonal processes governing the carbon dynamics in the Marsdiep basin, using a 30-month time-series. Loebl et al. (2007)

noted that the seasonality in the Wadden Sea leads to the area being predominantly heterotrophic in autumn and winter and net autotrophic in spring and summer. As such, yearly data sets are required to resolve the dynamics of this region and fully understand the biogeochemical coupling between the benthic and pelagic environments. The analysis performed here was undertaken in conjunction with supplementary data from the CANOBA project and CARBOOCEAN, which covered the entire North Sea basin during all 4 seasons from 2001-2002 (Thomas et al., 2005; Bozec et al., 2006) and a late summer cruise in 2008.

2 Methods

2.1 Area of Study

The time-series station is located in the Marsdiep basin, which is the largest tidal basin of the Wadden Sea, located southeast of the Wadden island Texel, adjacent to the North Sea (Figure 1). It is a shallow, estuarine environment with approximately 50% of the area consisting of tidal flats (van Beusekom et al., 1999). The Marsdiep is a distinctly unique environment due to the temporally variable input of freshwater from lake IJssel through the sluices of the Afsluitdijk. There are less significant freshwater inputs from the rivers Elbe, Weser and Ems (Lenhart et al., 1996) in the eastern Wadden Sea, and a fraction of Rhine river water is present, mixed in with the southern North Sea water (de Jonge, 1990). The main water exchange between the North Sea and the Wadden Sea occurs by tidal exchange in the southwest of the basin, through the Marsdiep basin (Ridderinkhof et al., 1990). The North Sea enters from the west, flowing along the southern boundary and mixes with the Wadden Sea water from the south, after which a fraction of this mixed water exits the basin along the northern boundary, where the sampling station is located (Figure 1).

Figure 1. Location of time series station in the Marsdiep basin of the Wadden Sea.

The western Wadden Sea is a very turbulent region due to tidally dominated currents and irregular topographical features. The time-series site is shallow with an average water depth of 7m (Schoemann et al., 1998) and the sediment is sandy with a silty surface layer

(Kieskamp et al., 1991). Primary production estimates show a wide range over several years, from $120 \text{ gC m}^{-2} \text{ y}^{-1}$ (Philippart et al., 2007) to $440 \text{ gC m}^{-2} \text{ y}^{-1}$ (Cadée and Hegeman, 2002). It has been estimated that 48% of the remineralization takes place in the sediment (van Beusekom et al., 1999), of which rates are highest in the summer months (Kowalski et al., 2012).

2.2 Sampling and Analysis

Samples were collected from ~1m depth using a niskin bottle on a fixed winch. The water column remains mixed all year-round, thus we assume that the 1m surface samples are representative of the entire water column. During the winter months (December - February) samples were taken on a monthly basis, increasing to weekly resolution through spring and summer (March - August) and then decreasing to bi-weekly sampling in autumn (September - November). Sampling consistently took place at high water, when the coastal southern North Sea water is the dominant water mass. Samples were chemically analyzed for dissolved oxygen, inorganic nutrients (ammonium (NH_4), nitrite (NO_2), nitrate (NO_3), phosphate (PO_4), silicate (Si(OH)_4)), chlorophyll α , dissolved inorganic carbon (DIC) and total alkalinity (A_T), and measurements of temperature and salinity were taken at the time of sampling.

The A_T and DIC samples were measured on a VINDTA 3C (Marianda, Kiel), which uses potentiometric titration with 0.1M hydrochloric acid to determine A_T and measures DIC using the coulometric method of Johnson et al. (1993). These parameters are measured with a precision of $\pm 2 \text{ } \mu\text{mol kg}^{-1}$ and $\pm 1 \text{ } \mu\text{mol kg}^{-1}$, respectively. Samples were collected in 250 ml durex glass bottles using tygon tubing following the standard sampling procedure outlined in DOE (Dickson, 2007). The samples were poisoned with 0.25 ml HgCl_2 after a volume of 5.25 ml was removed, creating a headspace of 5 cm^3 . Samples were taken in duplicate or triplicate and stored, in the dark, until analysis. All samples were measured within a year of sampling in batches of ~100 or more. Data quality was controlled using certified reference material (CRM, Batches #'s 86, 89, 100), acquired from Prof. Andrew Dickson at Scripps Institute of Oceanography (San Diego, California). The A_T titration data was re-processed after analysis to allow the inclusion of nutrient concentrations and salinity calibrations.

2.3 pCO₂ and pH calculations

From any two of the four measurable carbonate parameters it is possible to calculate the remaining two using thermodynamic principles. Here, measurements of A_T and DIC were used to calculate pCO₂ and pH using the Matlab version of CO2_SYS (Lewis & Wallace, 1998; van Heuven, 2009) with the carbonic acid dissociation constants of Mehrbach et al., (1973), refit by Dickson and Millero (1987). Both pH and pCO₂ were calculated at *in-situ* temperature and pressure and pH is reported on the total pH scale. The pCO₂ normalized to a constant, annual average temperature of 12°C (pCO₂@12°C) is also computed, to remove the temperature-driven changes in pCO₂.

2.4 Water mass calculations

The seasonal data from the CANOBA project was used to obtain a seasonally averaged salinity value in the region south of 56°N and west of 6°E. A simple mixing line was then applied between the measured salinity values in the Marsdiep and the relevant seasonal SNS end member to calculate the fraction of fresh water versus North Sea water.

3 Results

3.1 Seasonal and temporal patterns in the Marsdiep basin

Figure 2 shows the time series observations of temperature, salinity, ammonium (NH₄⁺), nitrate (NO₃⁻), nitrite (NO₂⁻), silicate (Si(OH)₄), phosphate (PO₄³⁻), apparent oxygen utilization (AOU = [O₂]_{sat} - [O₂]_{obs}), chlorophyll *a*, DIC, A_T, pCO₂ and pCO₂@12°C from May 2008 to October 2010. The seasonally averaged values of selected parameters are shown in Table 1, with the average monthly freshwater discharges from the sluices at Den Oever, at the Afsluitdijk.

Temperature follows the annual solar irradiance pattern of the northern hemisphere, with peak temperatures occurring in late summer (August) and the yearly minima occurring early in the year at the end of winter (February). The maximum temperatures for the three years showed little variation, peaking at 20.1°C for both 2008 and 2009, and 20.2°C in 2010. There is a general annual trend of lower salinities occurring in the Marsdiep in winter and a period of higher salinities throughout summer, with the annual peak in July. This pattern is consistent with decades of observations (Patsch and Lenhart, 2004) and explained through higher rainfall over the southwest European continent leading to higher river runoff during

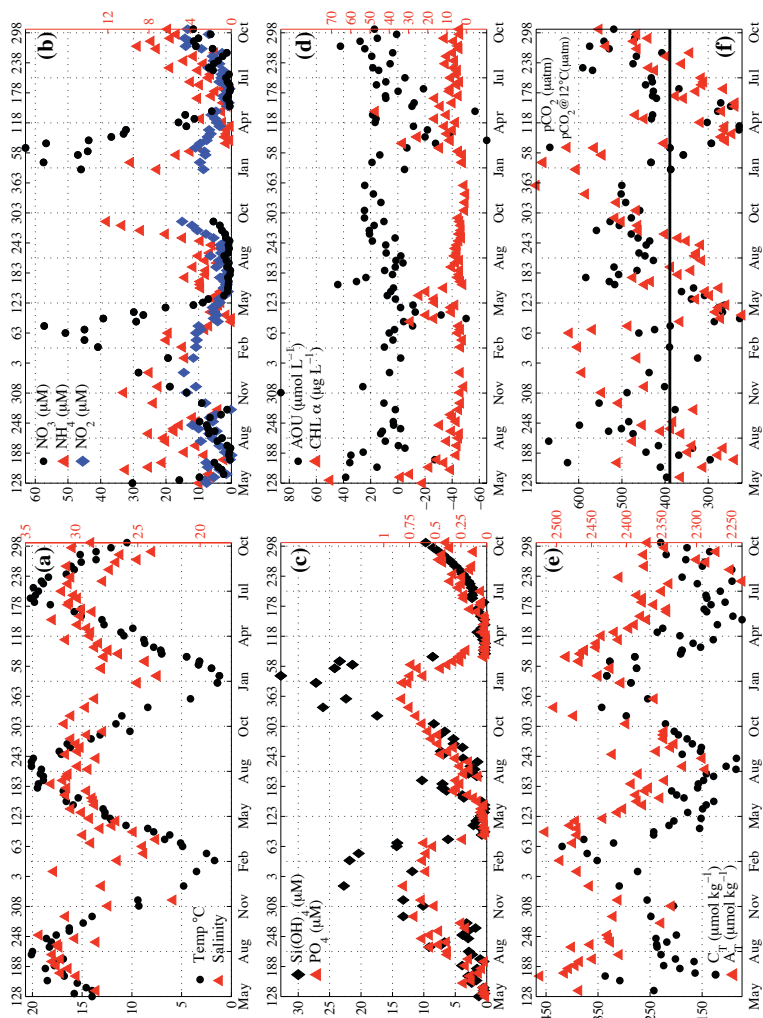

Figure 2. 30 Month time series plots of temperature (°C), salinity, ammonium (μmol l⁻¹), nitrate (μmol l⁻¹), nitrite (μmol l⁻¹), phosphate (μmol l⁻¹), silicate (μmol l⁻¹), AOU (μmol l⁻¹), chlorophyll α (μg l⁻¹), DIC (μmol kg⁻¹), A_T (μmol kg⁻¹) and pCO₂@12°C (μatm).

Table 1. Seasonally averaged values of measured parameters in the Marsdiep given with one standard deviation. Spring was defined as from yearday 60 to 151, summer is from yearday 152 to yearday 243, autumn is from yearday 244 to 334 and winter is from yearday 335 to 59. The numbers highlighted in red refer to the DIC and A_T samples taken during the time period, as fewer DIC and A_T samples were obtained compared to the other parameters.

winter compared to summer. There is large variability within the seasonal cycle of salinity and despite this broad pattern the minimum salinity (18.5) was recorded in early June and the maximum salinity (33.7) in early October. The highly variable freshwater output from the Afsluitdijk, combined with the influence of wind and tidal mixing in the Marsdiep, are likely to contribute towards some of the observed variability.

The concentration of inorganic nutrients throughout the years demonstrates clear seasonality linked to photosynthesis (Figure 2 (b)(c)). The nitrate, phosphate, and silicate concentrations all show a consistent pattern with peaks in the winter and minima in the spring or summer. A minimum concentration of nitrate is reached on yearday 165 in 2009 and yearday 150 in 2010, with concentrations of $0.8 \mu\text{mol l}^{-1}$ and $0.5 \mu\text{mol l}^{-1}$, respectively. Both years show a nitrate peak of $\sim 60 \mu\text{mol l}^{-1}$, on yearday 76 in 2009 and yearday 67 in 2010, which coincides with the respective minimum winter salinity value of each year. The ammonium annual trend shows a general offset to that of nitrate, however, is in phase with nitrite. Ammonium and nitrite also show a wintertime peak followed by a spring minimum, however, both fall approximately three months earlier than the respective peaks in nitrate. Concentrations of ammonium, in both 2009 and 2010, start to increase steadily from late spring.

In 2009, ammonium concentrations mirror the small peak in concentrations seen in phosphate, immediately following the initial depletion in spring. In 2009 there are two distinctive dips in phosphate concentration, the first closely following the peak in nitrate, on yearday 82, and the latter (yearday 216) slightly preceding the onset of increasing ammonium concentrations in late summer, which begin on yearday 231. In contrast, in 2010 a second period of decline in phosphate cannot be discerned, as the values stay close to zero throughout spring with a minimum reached on yearday 110. Phosphate concentrations show a close correlation to silicate concentrations, which are the first, of all the inorganic nutrients, to be depleted in the year, reaching values of 0.37 and $0.30 \mu\text{mol l}^{-1}$ by yearday 91 in 2009 and 95 in 2010, respectively. The respective maximum concentrations for these years, before the declines, were $21.81 \mu\text{mol l}^{-1}$, on yearday 34 in 2009 and $32.8 \mu\text{mol l}^{-1}$ on yearday 38 in 2010, representing respective decreases of $21.44 \mu\text{mol l}^{-1}$ and $32.5 \mu\text{mol l}^{-1}$ within the first three and a half months of the year.

Chlorophyll α concentrations show a general inverse relationship with apparent oxygen utilization ($\text{AOU} = [\text{O}_2]_{\text{sat}} - [\text{O}_2]_{\text{obs}}$), with both parameters showing large fluctuations over spring. Chlorophyll α peaks on yearday 85 in 2009, just before AOU reaches the yearly

minimum on yearday 91. The same pattern is seen in 2010 in early spring, with the minimum AOU (on yearday 82) closely following a peak in Chlorophyll α . However, in 2010, the yearly maximum of Chlorophyll α falls later in the year on the same day (yearday 140) as the second lowest AOU value.

The seasonal cycle of DIC and A_T in the Marsdiep reveal a tight coupling to each other, shown in Figure 2 (e) and Figure 3. Both parameters show the highest concentrations occurring in spring, when both maxima exceed their respective peaks in the adjacent southern North Sea (data not shown). Values then decrease until late summer, with minima observed in mid-August, after which, both DIC and A_T begin a steady increase again. The DIC minimum in 2009, on yearday 216, is observed much later in the year than in 2010, which falls on yearday 150. Despite the difference in timing, both DIC minima are within $10 \mu\text{mol kg}^{-1}$ of each other ($2073.9 \mu\text{mol kg}^{-1}$ in 2009 and $2083.3 \mu\text{mol kg}^{-1}$ in 2010). In contrast, the DIC peak of the whole 28 months falls in the winter of 2008-2009 and is $86 \mu\text{mol kg}^{-1}$ higher than the respective winter peak of 2009-2010, representing a 25% decrease in the annual range of DIC. Due to the non-conservative behavior of DIC in the presence of biological activity (spring and summer), we took the wintertime DIC and salinity values and regressed them with values taken from the adjacent southern North Sea to obtain the following equations:

$$2009: \text{DIC} = -14.6 \cdot S + 2728 \quad (R^2 = -0.99, \text{p-value: } 0.065)$$

$$2010: \text{DIC} = -14.3 \cdot S + 2662 \quad (R^2 = -0.94, \text{p-value: } 0.005).$$

Both regressions show a similar relationship, however the derived zero-salinity end-member in 2009 is $66 \mu\text{mol kg}^{-1}$ higher, explaining a large portion of the greater DIC range observed in this year. The annual A_T peak decreases from $2529 \mu\text{mol kg}^{-1}$ in 2009 to $2458 \mu\text{mol kg}^{-1}$ in 2010, however, similarly the range remains similar for both years ($247 \mu\text{mol kg}^{-1}$ and $223 \mu\text{mol kg}^{-1}$ for 2009 and 2010, respectively). Linear regression of salinity against A_T in the Marsdiep was insignificant, preventing us from deriving a similar A_T -salinity mixing line.

To further examine the changes in DIC and A_T throughout the year, seasonal linear regressions were performed between both parameters, revealing four statistically significant relationships (Figure 3). From summer to winter the regression slope showed little variation ($0.80 - 0.93$), however, with significant variation in the intercept. Such a relationship would suggest that the same processes are controlling the interaction between the two parameters for the majority of the year, but that the background A_T or DIC concentration is being further modified, independently of the other. The spring DIC- A_T relationship varied notably from

Figure 3. Seasonal linear regressions of DIC and A_T fitted using data from all three years. Fitting was performed using the least squares method, resulting in the following equations, with the correlation coefficient (R²) and p-value given in brackets:

Winter:	$A_T = 0.93DIC + 280$	[±23]	$[R^2=0.76, p=0.004]$
Spring:	$A_T = 0.41DIC + 1515.9$	[±25]	$[R^2=0.79, p=0.000]$
Summer:	$A_T = 0.80DIC + 638.8$	[±36]	$[R^2=0.80, p=0.000]$
Autumn:	$A_T = 0.82DIC + 542.3$	[±29]	$[R^2=0.80, p=0.000]$

that of the other seasons in that the gradient was approximately half that for the rest of the year (0.41) and the highest A_T intercept is observed.

The difference in winter DIC peaks between the years appear to have a negligible effect on the following years pCO_2 distribution, with the maximum pCO_2 values calculated in 2009 and 2010 falling within 8 μatm of each other (583.7 and 590.8 μatm , respectively). The respective annual minimum pCO_2 values were 190.53 and 205.36 μatm , occurring in spring. The annual cycle of calculated pCO_2 in 2009 exhibits two clear periods of depression (Figure 2(f)), the first one occurring in late winter and the second in late spring. The first depression is smaller than the second, however, both lead to under-saturation of CO_2 with respect to the atmosphere. In contrast, in 2010 the two peaks fall later in the year, the first minima occurring in early spring and the second in early summer. There is a small peak immediately following the initial dip, most evident in the temperature-normalized plot in 2010, where pCO_2 concentrations reach 431.8 μatm before falling to 248.2 μatm again. From July, in both years, the pCO_2 increases to above atmospheric concentrations, turning the Marsdiep into a temporary source of CO_2 . The temperature-normalized pCO_2 plot (Figure 2(f)) shows a similar pattern for most of the year, however, a greater portion of summer is undersaturated with respect to CO_2 .

The result of the water mass analysis is shown in Figure 4 as a function of discharge from the sluices of the Afsluitdijk (data Rijkswaterstaat, Henk Zemmeling, *pers. comm.*). The minimum fraction of southern North Sea water found in the Marsdiep basin was 54% in the early summer of 2008 (yearday 160), whereas the maximum fraction of 98% was found in October of the same year. The higher rates of discharge generally occur between October to May, thus resulting in slightly fresher water in the Marsdiep during these periods. It is only during these periods of higher discharge that a relationship between the fraction of freshwater and discharge volume can be observed. At discharges greater than $450 \text{ m}^3 \text{ s}^{-1}$, a significant linear relationship becomes apparent with an R^2 value of -0.67 (p-value of 0.006).

4 Discussion

4.1 Phytoplankton Dynamics

The depletion of silicate early in the year is caused by the first spring phytoplankton bloom of diatoms. The diatom bloom has been observed to peak close to yearday 92 (van Boekel et al., 1992), which is consistent with the silicate minima found here on yearday 91 and 95, in

Figure 4. The fraction of North Sea water, expressed as a percentage, present in the Marsdiep against freshwater discharge from the sluices at Den Oever ($\text{m}^3 \text{s}^{-1}$). The linear regression is applied to data with a discharge greater than $450 \text{ m}^3 \text{s}^{-1}$.

2009 and 2010, respectively. Phosphate limitation in the Marsdiep has been well documented (De Jonge, 1997; Phillipart et al., 2000) and the exhaustion of silicate occurred after phosphate concentrations had reached very low levels for both years. However, linear regression of phosphate against silicate for the duration of the bloom produces a positive intercept, indicating that silicate was the limiting nutrient of the bloom. Furthermore, the decline in pCO_2 observed during this period of the year is larger in 2010, the year in which wintertime silicate concentrations peaked $11 \mu\text{mol l}^{-1}$ higher than 2009. In 2009 there was a pCO_2 decline of $162.5 \mu\text{atm}$ associated with the exhaustion of silicate, and in 2010 the decrease was $227.3 \mu\text{atm}$. The phosphate and nitrate concentrations were similar for both years, suggesting that the greater silicate concentrations in 2010 facilitated additional primary production, supporting the argument that silicate acts as the limiting nutrient.

In both years, nitrate concentrations reveal a distinct decline immediately following silicate depletion, which is characteristic of the *Phaeocystis* bloom (van Boekel et al., 1992; Schoemann et al., 1998; Loebl et al., 2007). Linearly regressing nitrate against phosphate produces a negative intercept, which indicates nitrate was the limiting nutrient on this occasion. A substantial increase in microzooplankton is observed at the end of the *Phaeocystis* bloom (Loebl et al., 2007) and van Boekel et al. (1992) also noted a rapid increase in bacteria in the Marsdiep after the decline of the second bloom, which are indicative of the rapid uptake of the organic carbon into the microbial foodweb. Efficient remineralization is supported in our observations by increasing concentrations of ammonium occurring at the end of *Phaeocystis* bloom (Loebl et al., 2007).

The anticipated decline in $p\text{CO}_2$ associated with the *Phaeocystis* bloom is not as evident as that caused by the diatom bloom. In fact in 2009 there is just one data point (on yearday 118) showing a decrease in $p\text{CO}_2$, whilst the general trend is increasing. The same pattern is evident in $p\text{CO}_2@12^\circ\text{C}$, although to a lesser extent, thus this increasing trend can only partly be attributed to the effect of increasing temperatures. Figure 5 shows that the increase in $p\text{CO}_2$ during this time is accompanied by increasing AOU, suggesting that pelagic remineralization is greater than production resulting in a net $p\text{CO}_2$ increase. In 2010, a slightly different pattern is apparent. After the diatom bloom, $p\text{CO}_2$ increases to $431.8 \mu\text{atm}$ on yearday 125, at which point a period of decrease begins until yearday 150, where the second $p\text{CO}_2$ minimum occurs simultaneously with nitrate exhaustion. The concurrent decrease of $p\text{CO}_2$ with nitrate is accompanied by a small decrease in AOU (Figure 5), indicative that in 2010 the primary production within the *Phaeocystis* bloom was sufficiently large to outcompete the effects of remineralization on AOU.

Figure 5. Calculated $p\text{CO}_2$ (μatm) (from A_T and DIC) values through spring (yearday 59 – 151) and into summer (yearday 152 – 243), for the years 2009 and 2010. The boundary between spring and summer is denoted by the black line. Apparent oxygen utilization ($\mu\text{mol l}^{-1}$) is represented by the colourscale.

4.2 Effects of Phytoplankton on DIC

The effects of phytoplankton succession are evident in the $p\text{CO}_2$ concentrations, however, it is not as clear how it impacts the DIC concentration. Net community production (NCP) is the difference between gross primary production and respiration. In the adjacent southern North Sea a very similar NCP is calculated based on DIC to that calculated using dissolved inorganic phosphate (DIP) (Bozec et al., 2006; Brockmann et al., 1990). The similarity of the two different calculations of NCP indicates that NCP is similar to new primary production

where NPP is considered as primary production associated with the assimilation of newly available nitrate in accordance to Redfield stoichiometry ((106:16), Redfield, 1963; Dugdale and Goering, 1967). During the diatom bloom there is no indication of nutrient limitation or significant remineralization, thus we use the changes in nitrate and DIC concentration (ΔNO_3 and ΔDIC), assuming Redfield Stoichiometry, to get an indication of NPP and NCP for the two years.

Using ΔDIC and a water column depth of 7m we calculate the NCP of the Marsdiep during the diatom bloom as $0.95 \text{ mol C m}^{-2}$ in 2009 and $1.24 \text{ mol C m}^{-2}$ in 2010. Similarly, using ΔNO_3 and the Redfield ratio we calculate NPP as $0.85 \text{ mol C m}^{-2}$ in 2009, and $1.39 \text{ mol C m}^{-2}$ in 2010. Comparing these sets of values, there is a lower NPP compared to NCP in 2009, indicative that only ~90% of production was in fact NPP. In contrast, in 2010 the higher estimate of NPP compared to NCP indicates that only NPP was taking place. These results are consistent with the pattern of pCO_2 , however, as pCO_2 was calculated from DIC, this may contribute to the similarities. It was earlier suggested that higher silicate concentrations were responsible for facilitating a greater amount of production in 2010. As such, one would expect a relationship between the change in silicate concentration and change in NPP. Such a link is apparent when looking at the change in silicate peak from 2009 to 2010, which increased by 150% and the difference in the NPP, calculated from ΔNO_3 , which increased by 163% from 2009 to 2010. Whilst this is a rough approximation of NPP, as we do not account for contributions or loss by advection, the amount of new production during the spring diatom bloom does appear to be influenced by the wintertime silicate concentrations.

If we also take into account changes in phosphate throughout the diatom bloom, production occurs with a N:P ratio of 16:0.2 in both 2009 and 2010. Such an elevated ratio of $\Delta\text{NO}_3/\Delta\text{PO}_4$ indicates that phosphate may act as a limiting nutrient. However, the fact that further production occurs, on quite a large scale, past the point of phosphate depletion indicates that preferential recycling of phosphate is taking place (Thomas et al., 1999). During the diatom bloom the $\Delta\text{DIC}/\Delta\text{NO}_3$ ratio conforms quite well to that of Redfield (106:16), with ratios of 109:16 in 2009 and 115:16 in 2010. However, post-bloom it becomes significantly higher than that of Redfield's ideal ratio. This is likely to be further indication of preferential recycling of nitrate, however, the ratio of carbon to nitrate in *Phaeocystis* blooms has been shown to deviate significantly from that of Redfield (Schoemann et al., 2005).

4.3 DIC-associated variations in A_T

The seasonal relationship between A_T and DIC (Figure 3) shows a tight coupling, however, whilst DIC is strongly influenced by photosynthesis through direct uptake, the effect on A_T is smaller. Photosynthesis causes an overall positive change in A_T due to the uptake of nutrients and the shift in carbon chemistry. The production of 1 mol of organic matter (containing 106 mols of organic carbon) has been calculated to increase A_T by 17 mols (Chen et al., 1982). In the Marsdiep the observed DIC decreases by $109 \mu\text{mol kg}^{-1}$ and $182 \mu\text{mol kg}^{-1}$ during spring (yearday 60 – 151), which would correspond to A_T increases of $17.5 \mu\text{mol kg}^{-1}$ and $29.1 \mu\text{mol kg}^{-1}$. In contrast to this, A_T shows a distinctive decreasing trend during spring in the Marsdiep basin, with an associated ΔA_T of $-168 \mu\text{mol kg}^{-1}$ and $-102.17 \mu\text{mol kg}^{-1}$. The annual cycle of A_T in the Marsdiep (Figure 2(e)) is thus the direct inverse pattern to that of the A_T cycle in the SNS (Thomas et al., 2009), indicative of the dominance of different biogeochemical processes.

As we lack data for the freshwater end member of A_T and DIC it is not possible to derive a reliable linear relationship with salinity. Instead we use the seasonally derived linear relationships between A_T and DIC and the fact that both are conservative properties, with regard to temperature and pressure, to calculate the predicted changes in A_T associated with DIC changes, between seasons. Any observations deviating from these relationships are indicative of DIC-independent A_T sources or sinks operating at that time of year. Such a method should also, to an extent, take into account changes caused by fluctuations in the freshwater end member concentrations, as both parameters should co-vary with such changes. During autumn and winter, when temperature and light availability limit primary production, the DIC associated changes in A_T extend to remineralization processes. However, in spring and summer the generation of DIC through pelagic remineralization will be masked as the newly available DIC is quickly removed again from the water column by phytoplankton. Therefore, A_T generated from remineralization processes, although limited in spring and summer, will have to be considered as DIC-independent, and accounted for.

In 2009 the change from the maximum winter concentration of DIC to the minimum spring concentration of DIC is $-277 \mu\text{mol kg}^{-1}$, with a calculated associated change in A_T (ΔA_T) of $-123 \mu\text{mol kg}^{-1}$, using the seasonal DIC- A_T regressions. This value is close to the observed ΔA_T of $-168 \mu\text{mol kg}^{-1}$, leaving just $-45 \mu\text{mol kg}^{-1}$ A_T unaccounted for. For 2010 the observed ΔDIC of $-260 \mu\text{mol kg}^{-1}$ has a calculated, associated ΔA_T decrease of $-72 \mu\text{mol kg}^{-1}$. The observed ΔA_T decrease was $-102 \mu\text{mol kg}^{-1}$, leaving $-30 \mu\text{mol kg}^{-1}$ to an independent A_T sink. As the water column is saturated with respect to oxygen throughout this

period, the two most likely processes contributing to such a decrease in A_T are nitrification and the uptake of ammonia. Nitrification is the oxidation of ammonium to nitrite and nitrate, and has been found to peak in spring and late summer in the Wadden Sea (Jensen et al., 1996), when oxygen is still readily available. Furthermore, more recently, net nitrification has also been found to take place in Dutch coastal waters during winter (Wuchter et al., 2006). For every mole of nitrate produced by nitrification, A_T decreases by 2 moles, following the below two equations:

If the entirety of the unaccounted for sink of A_T was due to nitrification from remineralization there would be an equivalent, release of $360 \mu\text{mol kg}^{-1}$ of DIC in 2009 and $240 \mu\text{mol kg}^{-1}$ of DIC in 2010. The lack of an observed increase in DIC is unsurprising, as it would be largely mitigated by the ongoing primary production. The uptake of ammonia is also likely to contribute to the decrease in A_T . Over the time period in question we observe a $12 \mu\text{mol l}^{-1}$ decrease in ammonia, which, if was completely due to biological uptake would cause a decrease of $24 \mu\text{mol kg}^{-1}$ in A_T . As such, ammonia uptake could constitute half of the A_T sink, however, a proportion of the decrease in ammonium will be caused by ongoing nitrification. Thus in what ratio these processes take place cannot be determined here.

The concurrent increase of DIC and A_T from late summer to winter results in both peaking simultaneously, for both years. In 2009 the DIC concentration starts to increase from yearday 238 to its peak on yearday 340, however, in 2010 the increase starts earlier on yearday 227 peaking on yearday 350. Following the same method as from winter to spring, we assess the ΔDIC and ΔA_T from autumn, just after the DIC minimum, to winter. The total observed ΔDIC from autumn to winter, for the two years, is $+192 \mu\text{mol kg}^{-1}$ and $+238 \mu\text{mol kg}^{-1}$, respectively. The concomitant observed ΔA_T is smaller, with values of $+148 \mu\text{mol kg}^{-1}$ and $+195 \mu\text{mol kg}^{-1}$ for 2009 and 2010, respectively. Using the DIC- A_T regressions we calculate ΔA_T values of $+137 \mu\text{mol kg}^{-1}$ and $+174 \mu\text{mol kg}^{-1}$, respectively. These values are representative of the observed values, indicating that the dominant controls on A_T are accounted for by those processes related to the remineralization of DIC. The deviation between the calculated and observed values may be attributable to changes in the freshwater end member properties.

Aerobic oxidation of organic matter leads to a decrease in A_T , following the reaction:

A high AOU in autumn makes it unlikely that this will constitute a significant process at this time of year. In the absence of oxygen the next electron acceptor is nitrate, in the process of denitrification. The reaction can be written in full as (Chen and Wang, 1999):

which leads to an increase in A_T of 83.8 mol per mol of organic matter. Denitrification has been observed in the sediment of the Marsdiep, beginning in late summer and increasing throughout winter (Kieskamp, 1991). Denitrification in other areas of Wadden Sea sediments have demonstrated rates up to $0.19 \text{ mmol N m}^{-2} \text{ h}^{-1}$, and have even been found to take place in oxic conditions (Gao et al., 2010). Assuming a maximum sediment remineralization rate of 90%, which is representative of the region (van Beusekom et al., 1999), $194 \text{ } \mu\text{mol kg}^{-1}$ of DIC (observed in 2009) remineralized with nitrate as electron acceptor, should release $137 \text{ } \mu\text{mol kg}^{-1}$ of A_T , and $238 \text{ } \mu\text{mol kg}^{-1}$ of DIC (observed in 2010) would release $169 \text{ } \mu\text{mol kg}^{-1}$ of A_T . These values are very similar to the observed change in A_T , strongly indicative that the majority of organic matter was remineralized via this process.

Sulfate reduction has also been found to be responsible for a significant proportion of carbon remineralization in the sediments of the Wadden Sea (Al-Raei et al., 2009) and has also been proposed as a significant contributor of A_T generation in the Wadden Sea (Thomas et al., 2009). Sulfate reduction releases both DIC and A_T into the water column, and thus it may also contribute to the observed autumn increase in both of these parameters. Furthermore, the reduction of trace metals has also been shown to contribute significantly to A_T in the East China Sea (Chen and Wang, 1999). Schoemann et al. (1997) observe a seasonal release of dissolved Mn and Fe in the Marsdiep associated with anoxic conditions in the sediment caused by the spring diatom and *Phaeocystis* blooms. It should be noted that a large number of these processes take place in the sediment and are reversed when the products enter an aerobic environment again. Unfortunately, the contribution of A_T from the sediment cannot be distinguished from that generated in the pelagic environment without additional data.

5 Conclusions

The results of 30 months of observations in the Marsdiep basin of the Wadden Sea suggest a

very close coupling between inorganic carbon dynamics, phytoplankton succession and the nitrogen cycle. The diatom spring bloom is almost exclusively NPP resulting in substantial under-saturation with respect to $p\text{CO}_2$ in the surface waters and turning the Marsdiep into a seasonal sink for CO_2 . The bloom is ultimately silicate limited in both years, thus in 2009 the NCP calculated for the diatom bloom was just $0.95 \text{ mol C m}^{-2}$, whereas in 2010, with a 48% increase in wintertime silicate concentration, the NCP was $1.24 \text{ mol C m}^{-2}$. Non-redfield ratios during the subsequent *Phaeocystis globosa* bloom, and ongoing preferential nutrient recycling prevent such a calculation being performed for biological production taking place later in the year.

There is a significant linear relationship between A_T and DIC for all four seasons, in both years. Whilst the annual DIC cycle mirrors that of the adjacent sNS, the A_T displays the inverse seasonal relationship to that of the sNS. We attribute A_T consumption, through spring and into summer, to nitrification and ammonia uptake, however, the ratio in which they occur cannot be constrained here, and is likely to vary within the time period. From autumn through to winter A_T is produced in quantities consistent with denitrification of 90% of the organic matter produced. While this is likely the dominant ongoing process at this time, the reduction of sulfate, manganese and iron is also likely to contribute to A_T generation and we suggest further work on sediment fluxes in the area to better constrain an A_T budget.

Chapter 4

Variability of North Sea pH and CO₂ in response to North Atlantic Oscillation forcing.

Lesley A. Salt, Helmuth Thomas, A. E. Friederike Prowe, Alberto V. Borges, Yann Bozec,
and Hein J. W. de Baar.

Abstract

High biological activity causes a distinct seasonality of surface water pH in the North Sea, which is a strong sink for atmospheric CO₂ via an effective shelf pump. The intimate connection between the North Sea and the North Atlantic Ocean suggests that the variability of the CO₂ system of the North Atlantic Ocean, may, in part be responsible for the observed variability of pH and CO₂ in the North Sea. In this work we demonstrate the role of the North Atlantic Oscillation (NAO), the dominant climate mode for the North Atlantic, in governing this variability. Based on three extensive observational records covering the relevant levels of the NAO index, we provide evidence that the North Sea pH and CO₂ system strongly responds to external and internal expressions of the NAO. Under positive NAO the higher rates of inflow of water from the North Atlantic Ocean and the Baltic outflow leads to a strengthened north-south biogeochemical divide. The limited mixing between the north and south leads to a steeper gradient in pH and partial pressure of CO₂ (pCO₂) between the two regions in the productive period. This is exacerbated further when coinciding with higher sea surface temperature, which concentrates the net community production in the north through shallower stratification. These effects can be obscured by changing properties of the constituent North Sea water masses, which are also influenced by NAO. Our results highlight the importance of examining inter-annual trends in the North Sea CO₂ system with consideration of the NAO state.

1. Introduction

Coastal and marginal seas play an important role in the atmosphere-ocean carbon exchange, responsible for a disproportionately large amount of primary production relative to their surface area [Gattuso *et al.*, 1998], which is triggered by large inputs of nutrients and organic carbon from the adjacent ocean, land and atmosphere [Wollast, 1998; Thomas *et al.*, 2005a; Thomas *et al.*, 2008]. The export of this carbon into the adjacent open ocean, thus sequestering large quantities of anthropogenic CO₂, is known as the continental shelf pump [Tsunogai *et al.*, 1999; Thomas *et al.*, 2004]. The effectiveness of this pump is related to the physical and biological conditions governing the CO₂ disequilibrium between the atmosphere and the sea surface, which in turn is thermodynamically responsible for the CO₂ uptake and the subsequent variation in pH and partial pressure of CO₂ (pCO₂). The codependence of this variability on physical and biological factors makes it difficult to discern the increase in CO₂ solely attributable to atmospheric pCO₂ increases [Santana-Casiano *et al.*, 2007].

The North Sea is a shelf sea on the northwest European continent with links to the North Atlantic Ocean in the south and the north. The majority of water exchange with the North Atlantic occurs in the northern North Sea, where inflowing waters enter through the Orkneys-Shetland shelf, Shetland shelf and the Norwegian channel, with the Norwegian Trench providing the main exit pathway of circulated water out of the North Sea [Otto *et al.*, 1990; Winther and Johannessen, 2006]. The total net carbon export to the North Atlantic via the Norwegian Trench has been estimated to be $6 \pm 1 \times 10^{12}$ mol C yr⁻¹ [Wakelin *et al.*, 2012], which includes more than 90% of the CO₂ drawn down from the atmosphere in the North Sea [Thomas *et al.*, 2005a]. The effectiveness of the North Sea CO₂ pump is determined principally by water mass exchange between the North Sea and the North Atlantic Ocean in combination with the export of carbon out of the surface layer, predominantly as sinking particulate organic matter [Thomas *et al.*, 2004; Bozec *et al.*, 2005]. The latter applies most significantly to the deeper (>50 m), seasonally stratified northern part of the North Sea (>56°N), where seasonality in pH is controlled by production of organic matter and its export [Thomas *et al.*, 2009]. The seasonality of pH and pCO₂ in the southern North Sea is also closely coupled to primary production, however the export of organic matter is reduced by the rapid remineralization, which takes place in the shallow (<50 m) and well-mixed water column [Borges and Frankignoulle, 1999, 2002; Schiettecatte *et al.*, 2006, 2007].

Over the North Atlantic Ocean, a number of atmospheric teleconnection patterns influence climate variability of which the North Atlantic Oscillation (NAO) is the most prominent. The NAO Index (NAOI) is defined as the difference of atmospheric sea level pressure (SLP) between the Icelandic low and the Azores high and accounts for the greatest proportion (>30%) of the observed SLP variance in the region from December to March [Hurrell, 2003]. The effects of the NAO control a number of large-scale processes at different timescales [e.g. Hurrell, 1995; Hurrell and Loon, 1997; Greatbatch, 2000]. Since the atmospheric pressure anomalies are most pronounced during northern hemisphere winter [Greatbatch, 2000] and the ratio of signal to noise is the highest [Hurrell and Loon, 1997], commonly (but not exclusively) the NAOI recorded during December, January and February (DJF), has been referred to in the literature yielding the most accentuated NAOI variability. Thus, although the NAOI is commonly established for DJF consequences of the NAO have been identified at various timescales. While the atmospheric realm responds at immediate, shorter timescales, for example via variability of trajectory, direction and strength of winds, the oceanic system responds at times scales from seasons to decades, for example via altered circulation patterns at various spatial scales [e.g. Hurrell, 1995; Hurrell and Loon, 1997, Greatbatch, 2000; Thomas *et al.*, 2008a]. Modeling studies [Thomas *et al.*, 2008; Levine *et al.*, 2011; McKinley *et al.*, 2011] and long-term observations [Santana-Casiano *et al.*, 2007; Pérez *et al.*, 2010; Bates, 2011] suggest that NAO-driven changes exert significant control over the inter-annual variability of hydrographic properties and in turn the uptake of CO₂.

Recently, observations from the North Sea [Thomas *et al.*, 2007] and the North Atlantic Ocean [Watson *et al.*, 2009] indicate that the surface water pCO₂ has risen faster than the atmospheric pCO₂, which has been linked to the effects of the NAO, with varying time-scales of effect across the region [Santana-Casiano *et al.*, 2007; Thomas *et al.*, 2008a]. In-depth discussions of the role of the NAO in regulating the climate and weather go beyond the scope of the present paper, and can be found elsewhere, for example in Hurrell [1995], or Greatbatch [2000]. However, within the North Sea many processes have demonstrated significant correlations with the wintertime (DJF) NAOI, which, as we later show, impact the carbonate system. The strength of the water mass exchange between the North Atlantic and the North Sea is regulated by the NAO, which in turn affects physical and chemical characteristics of the North Sea water column for the annual cycle. As a consequence of enhanced water mass exchange between North Atlantic and North Sea during years of positive NAOI (NAO+)[Winther and Johannessen, 2006; Kühn *et al.*, 2010], the corresponding increase of the North Sea's nutrient inventory leads to higher productivity throughout the productive season from spring until the end of summer [Pätsch and Kühn, 2008]. Characteristic in the North Sea's response to NAO forcing can also be a hysteresis

between cause and effect: In the North Sea NAO+ has further been associated with higher precipitation across Scandinavia with drier conditions over central Europe [Ionita *et al.*, 2011]. Changes in precipitation patterns over the drainage area of the Baltic Sea during winter will affect the runoff from the Baltic Sea into the North Sea over the relevant (runoff) seasons. Additionally, stronger westerly winds during winter, correlated with a positive wintertime NAOI, push North Sea water into the Baltic Sea, a process that in turn leads to an enhanced outflow from the Baltic Sea into the North Sea during the subsequent spring and summer [Hordoir and Meier, 2010]. These patterns are generally reversed during a NAO negative (NAO-) state. From these few examples it is evident that despite the fact that the NAOI is commonly established for winter (DJF), the consequences for the North Sea are complex, not restricted to the winter season, and can be (partly) masked or even overridden by local or regional weather. One of the primary aims of this paper is to unravel this complex situation and to understand the variability of the North Sea CO₂ system in front of this background.

The intra-annual variability of pCO₂ and dissolved inorganic carbon (DIC) has been well documented in the North Sea [Frankignoulle and Borges, 2001; Thomas *et al.*, 2005b; Prowe *et al.*, 2009; Bozec *et al.*, 2006; Omar *et al.*, 2010; Artioli *et al.*, 2012], however, on long time scales little work has been done [Thomas *et al.*, 2005a; Thomas *et al.*, 2007; Borges and Gypens, 2010] and despite the proximity of the North Atlantic, the drivers for inter-annual variability of the CO₂ system in relation to the North Atlantic variability, have not yet been investigated from field observations. Further, the full scope of variations in pH and pCO₂ are still difficult to constrain when attempting to reproduce them in models [Prowe *et al.*, 2009; Gypens *et al.*, 2011; Lorkowski *et al.*, 2012; Artioli *et al.*, 2012]. Relying on a unique data set covering three basin-wide occupations of the North Sea during all relevant NAO phases, we are now able to examine the influences of NAO forcing on the North Sea carbonate system, which exerts control over internal and external processes affecting the North Sea basin.

2. Materials and Methods

The North Sea was sampled during August/September 2001, 2005 and 2008 using a station grid of approximately 90 identical stations each time [Bozec *et al.*, 2005, 2006]. These years experienced NAO (DJF) indices of -1.9, 0.12 and 2.1, respectively (<http://www.cgd.ucar.edu/cas/jhurrell/indices.html>, 2012). As we examine the influence of

the NAO in the North Sea on different time scales, we assume that the wintertime NAO forcing will be responsible for producing the most prominent signal in the data on a basin-wide scale.

Due to greater spatial coverage of DIC and pCO₂ data, in all three years, compared to that of total alkalinity (A_T) and pH, the latter two were calculated from the former two, as previously done in inter-comparison studies [Thomas *et al.*, 2009]. Internal consistency studies from cruises with full carbonate parameter coverage in late summer indicate that A_T and pH can be predicted, using DIC and pCO₂, with an accuracy of $\pm 9 \mu\text{mol kg}^{-1}$ and ± 0.008 , respectively [L.A. Salt, *manuscript in preparation*, 2014]. Only stations with valid values for DIC and pCO₂ for all of the three years were used, resulting in a total of 85 stations worth of data for comparison.

2.1 DIC and pCO₂

Samples for the carbonate parameters were obtained following the operating procedures outlined in DOE (2007). Carbonate system parameters, DIC, A_T and pH (in 2005) were determined at 8-15 depths per station, yielding approximately 700 samples per cruise. All samples were analyzed within 12 hours of sampling, and were verified for quality control using certified reference material (CRM) supplied by Prof. Andrew Dickson (Scripps Institute of Oceanography, USA). A single sample was obtained for both DIC and A_T and these were determined by coulometric and potentiometric titrations, respectively. For further details please see Thomas *et al.*, [2007].

Surface water pCO₂ was measured every minute using a flow-through system with continuous equilibration and infrared detection [Körtzinger *et al.*, 1996], yielding approximately 20000 measurements per cruise with an accuracy of $\pm 1 \mu\text{atm}$. A temperature-normalization was applied to the pCO₂ data to obtain pCO₂@16°C, which is independent of temperature differences between the years [Takahashi *et al.*, 1993].

2.3 Calculations

2.3.1 Water Mass Analysis

The North Sea surface waters (5 m depth) were separated into three simpler constituents using a mixing analysis of the dominant water masses in the North Sea [Kempe and Pegler, 1991; Shadwick *et al.*, 2011], with North Atlantic water, Baltic Sea water and German Bight water as end-members. The latter two consist of a fraction of North Atlantic water, however, the large freshwater contribution makes both very distinct from North Atlantic water and allows us to track them into the central North Sea. In order to differentiate water mass fractions from n number of contributors, $n-1$ end member variables are required. As this decomposition was done for the surface waters, temperature cannot be used, because due to seasonal heating and cooling it is not a conservative tracer as used in traditional multi-parametric optimizations for analysis of deep waters. Salinity, DIC and A_T all offer sufficiently distinct end member concentrations to be used, however, the co-dependence of A_T on salinity makes DIC favorable. The DIC is non-conservative due to biological uptake/release of CO_2 , however, the end members used (Table 1) are sufficiently distinct that changes in DIC concentration affected by mixing are much greater than the potential interference of primary production/respiration. This was confirmed by similar results being obtained using salinity and A_T , which is more conservative with respect to primary production.

DIC ($\mu\text{mol kg}^{-1}$) and salinity end members	2001	2005	2008
North Atlantic	2047 (35.06)	2078 (35.30)	2065 (35.13)
Baltic	1530 (8)	1530 (8)	1530 (8)
German Bight	2090 (30.36)	2012 (30.77)	2149 (32.28)

Table 1. Dissolved inorganic carbon and salinity end members. The DIC end members used for the water mass fraction calculation for the three years, with the corresponding salinity values in parentheses.

The end members for the North Atlantic and German Bight were determined individually for each year, with only the Baltic end member remaining constant. As we lacked observations in the Baltic Proper, DIC and A_T values were taken from literature for a representative salinity of 8 [Thomas and Schneider, 1999; Hjalmarsson et al., 2008](Table 1). The North Atlantic end member was determined by the maximum surface salinity found in the northwest North Sea (Latitudes $> 58^\circ\text{N}$ and Longitudes $< 0^\circ\text{E}$) and its corresponding DIC value. The German Bight end member was determined by the salinity and DIC value found at the station closest to the Elbe river mouth (54.75°N , 8.25°E). By using annually determined end members for the three years, we can rule out any change in water mass fractions occurring due to changes in the chemical signal of end members, which we later show does occur in the North Sea. Statistics describing the calculated water mass fractions are shown in Table 2.

Water Mass	2001			2005			2008		
	Range	Av.	Med.	Range	Av.	Med.	Range	Av.	Med.
North Atlantic	0-100	83	91	0-100	81	87	0-100	84	91
Baltic	0-16	2	0	0-15	3	1	0-20	3	7
German Bight	0-100	15	4	0-100	16	10	0-100	13	1

Table 2. Statistics of the different water mass fractions present in the North Sea in 2001, 2005 and 2008. The basin-wide range of values, average and median are given with the units representing the % of the total water present in the North Sea.

2.3.2 DIC Inventory Calculation of the North Sea

To quantify the changes in DIC between years, differences in biological activity and remineralization must be accounted for. Here we use the apparent oxygen utilization ($\text{AOU} = [\text{O}_2]_{\text{sat}} - [\text{O}_2]_{\text{obs}}$) to account for production and remineralization, applying the Redfield ratio [Anderson and Sarmiento, 1994] in the following equation:

$$\text{DIC}^* = \text{DIC} - (\text{AOU} \cdot 0.7).$$

These values were integrated throughout the water column to a common maximum depth per station, and then station totals were extrapolated over the entire North Sea basin. To help us

better understand the changes, the International Council for the Exploration of the Sea (ICES) defined boxes [ICES, 1983] were used to examine the regional changes in DIC and salinity. Unless specified otherwise, boxes 1- 5 refer to the entire water column, not just the upper 30m, whereas boxes 11- 15 refer to the deep (>30 m) portion of these boxes, respectively.

2.3.3 Calculation of Brunt-Väisälä frequency squared.

To assess the vertical stability of the water column in the northern North Sea (>56°N) we utilized the Brunt-Väisälä frequency squared:

$$N^2 = (-g/\rho) \cdot (\partial\rho/\partial z)$$

where z is the depth (m), ρ is density (kg m^{-3}) computed following the density equation of *Fofonoff and Millard* [1983] and g is the gravitational acceleration (9.807 m s^{-2}). The temperature and salinity data from the conductivity-temperature-depth (CTD) casts with a 1 m resolution were smoothed using a cubic spline. The N^2 was calculated from the smoothed dataset and the depth at which the maximum N^2 occurs we defined as the mixed-layer depth.

3. Results

The main distribution pattern of the carbonate parameters is relatively constant between years (Figure 1). The brackish Baltic outflow around the Norwegian headland has low A_T and DIC signals. The German Bight, in the southwest, is distinguished by its high A_T and high DIC content. The Shetland shelf represents the main North Atlantic inflow site, and is clearly identified by notably higher A_T values than the basin-wide average (Figure 1 (b)). The anti-correlated pH and $p\text{CO}_2$ both show a strong gradient at the 50 m depth contour, representing the boundary at which the dominant control on $p\text{CO}_2$ changes from temperature, in the well-mixed south, to biology, in the stratified north [Prowe *et al.*, 2009; Thomas *et al.*, 2005b]. The gradient between the north and south is steepest in 2008, closely followed by 2001, and weakest in 2005. This pattern reflects the measured surface water temperatures in the North Sea, 2001 and 2008 being the warmest (mean surface temperatures of 16.2°C (± 1.3) and 16.1°C (± 1.1), respectively), and 2005 the coldest (15.4°C (± 1.0)). The highest northern pH values and lowest $p\text{CO}_2$ values are observed in the northern North Sea in 2001, with progressively decreasing mean pH and increasing mean $p\text{CO}_2$ trends over time. The average surface DIC increased by $21 \mu\text{mol kg}^{-1}$, although not uniformly, and the average surface A_T remained relatively constant, $\pm 4 \mu\text{mol kg}^{-1}$, throughout all three years.

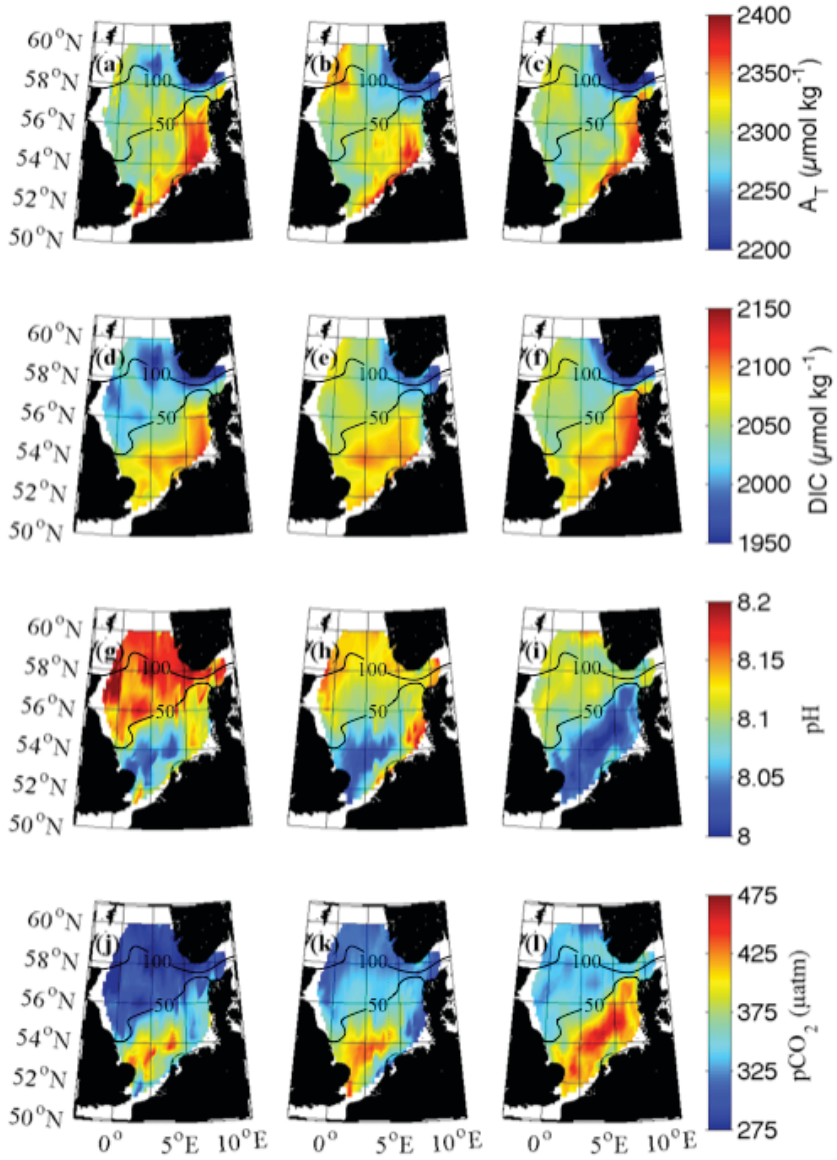

Figure 1. Surface layer distribution of carbonate parameters with 50 and 100 meter depth contours. **a-c,** total alkalinity ($\mu\text{mol kg}^{-1}$) for the years 2001, 2005 and 2008, **d-f,** dissolved inorganic carbon ($\mu\text{mol kg}^{-1}$) for the years 2001, 2005 and 2008, **g-i,** pH for the years 2001, 2005 and 2008, and **j-l,** partial pressure of CO_2 (pCO_2 ; μatm) for the years 2001, 2005 and 2008. The DIC and pCO_2 are observations, A_T and pH are calculated parameters from DIC and pCO_2 , using carbonic acid dissociation constants of *Mehrbach et al.*, 1973, refit by *Dickson and Millero* (1987), and pH is given on the Total scale. Average values for 2001, 2005 and 2008 are 2299, 2298 and 2291 $\mu\text{mol kg}^{-1}$ for A_T , respectively, 2034, 2052 and 2055 $\mu\text{mol kg}^{-1}$ for DIC, 8.129, 8.105 and 8.079 for pH and 323, 344 and 369 μatm for pCO_2 .

The North Sea CO₂ system is largely governed by the relative contribution of different water masses composing the North Sea water as well as the rate at which these are circulated within the North Sea shelf. The mixing analysis (Figure 2(a)) clearly identifies the North Atlantic Ocean water as the dominant water mass, constituting an average 83% fraction throughout all three years (Table 2). The average, basin-wide fraction of Baltic water increases from 2% in 2001 to 3% in 2005 and 2008 (Table 2). The dominant North Atlantic inflow follows an anti-clockwise circulation from the north, mixing in the south with German Bight water. In the northeastern areas the Baltic Sea outflow plays an additional role where it is introduced to the circulation on its way out of the North Sea. This leads to the presence of two main mixing regimes, one consisting of North Atlantic and German Bight water, and the other of North Atlantic and Baltic water (Figure 2(a)). It can be seen that in 2008 these two regimes are most distinguishable, which corresponds to the year in which the maximum Baltic fraction was recorded (20%; Table 2). The formation of the two mixing environments is reflected in the formation of a dichotomy in pH measurements in 2008, which is absent in 2001 and 2005 (Figure 2(b-d)). The dichotomy divides the North Sea, with more acidic waters in the south and higher pH values in the north. The divide is formed at, approximately, the 50 m depth contour accounting for the strong gradient visible in Figure 1(i) and (l).

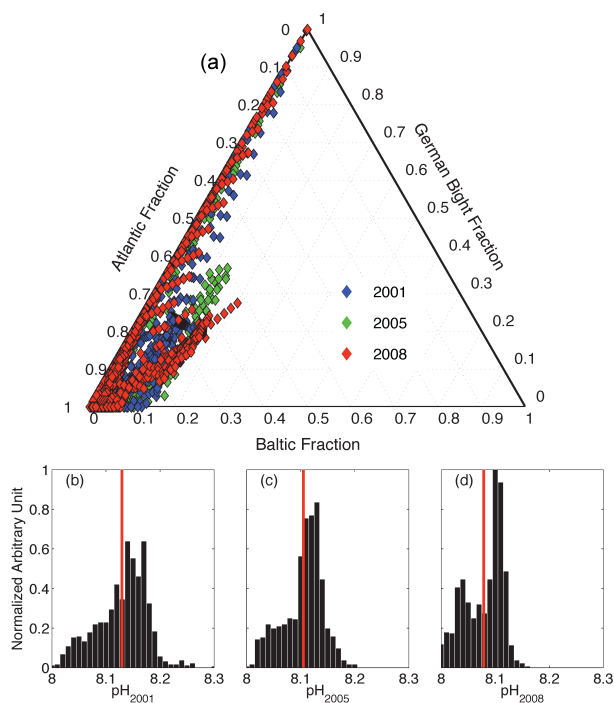

Figure 2. Water type contributions to the North Sea. **(a)** The fractions of North Atlantic water, Baltic water and German Bight water in the North Sea in 2001 (blue), 2005 (green) and 2008 (red). **(b)-(d)**, histograms of the frequency of calculated pH values binned in 0.01 pH unit intervals with the mean value per year marked by the red line.

Examining the mixing relationship between the North Atlantic and Baltic water further reveals a change in the water mass end members from 2001 to 2005. A linear regression was applied, for each year, to data with a Baltic water mass fraction greater than the three-year average of 3% (Figure 3) revealing three statistically significant relationships. The years 2005 and 2008 show a remarkably similar mixing line with the most notable difference being a general decrease in the salinities observed in the Skagerrak in 2008 compared to 2005. Such a shift is reflective of different proportions of the two water masses but indicates that the water masses remain constant in their properties. The difference between these two years and 2001, however, is much greater. The slope of the regression line is shallower in 2001, indicative of a higher DIC Baltic end member and a lower DIC North Atlantic end member. The same relationship is reflected, between 2005 and 2008, in the A_T mixing diagram (Figure 3(b)).

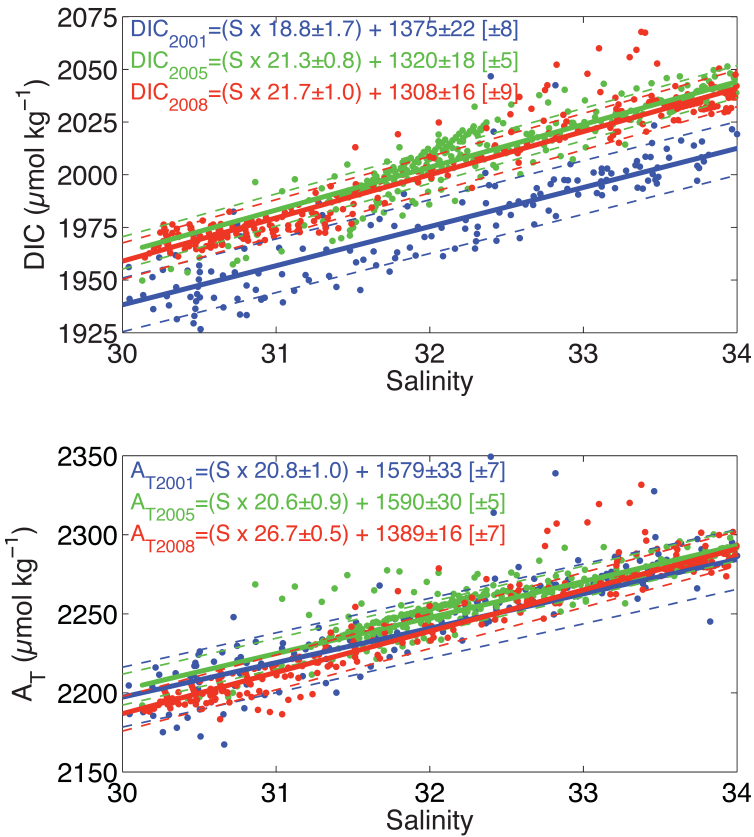

Figure 3. North Sea – Skagerrak mixing diagram. Linear fitted regressions for the mixing relationship between the Skagerrak and North Atlantic inflow in the northern North Sea. Upper graph shows DIC and lower graph shows A_T . Points were selected based on percentage of Baltic water mass fraction present ($>3\%$). Dashed lines represent one standard deviation ($\pm 1\sigma$) of the residuals for each fit, also given in parentheses.

The inorganic carbon, after correction for metabolic DIC (calculations in section 2.3.2) and respective salinity inventories were used to quantify the changes (ΔS and ΔDIC) between the two time periods. The change in each ICES box for the two time periods showed a significant correlation coefficient of 0.903 and 0.839 (excluding Box 8) for the period 2001-2005 and 2005-2008, respectively. Box 8, heavily influenced by the German Bight, recorded very low salinities for 2008, coinciding with a larger Elbe discharge [GKSS, 2012, <http://coast.gkss.de/staff/kappenberg/elbe/abfluss/elbe.abfluss>]. This box is likely to be more representative of local effects thus skewing the general pattern for the rest of the North Sea (including box 8 gives a $R^2 = 0.49$). Although the increase in DIC was basin-wide from 2001 to 2005, it did not occur evenly across the basin or throughout the water column.

The greatest increases in average DIC concentration from 2001 to 2005 occurred in the central and northwestern North Sea. The latter region is significantly deeper than the southern North Sea, thus the ICES boxes were further divided into a surface (30m) and deep box. The surface boxes showed an increase of the same order of magnitude as the deep boxes, however, due to the greater DIC concentrations at depth this constitutes a lower percentage of total increase. From 2005 to 2008 the changes in DIC were much smaller and demonstrated no clear pattern. The North Sea DIC inventory was 8.11 Pg C (1 Pg = 10^{15} g) in 2001, 8.17 Pg C in 2005 and 8.18 Pg C in 2008. Hence, it increased by approximately 0.8% ($+ 6 \times 10^{-2}$ Pg C) from 2001 to 2005, while the inventory remained almost stable ($+ 5 \times 10^{-3}$ Pg C, $<0.1\%$) between 2005 and 2008. The deep northern boxes demonstrated a greater inventory increase of 1.1% from 2001 to 2005, and a 0.0% change from 2005 to 2008. Of the entire observed change in these boxes, 97% occurred from 2001 to 2005.

The changes in the DIC concentrations in the surface also manifest in the change in temperature-normalized pCO_2 ($pCO_2@16^\circ C$) distribution (Figure 4). The increase in the average North Sea $pCO_2@16^\circ C$ from 2001 to 2005 is 26 μatm , compared to 4 μatm from 2005 to 2008 (the increases for 2001 to 2005 and 2005 to 2008 for non-temperature normalized pCO_2 were 21 μatm and 25 μatm , respectively). Using an average basin-wide $pCO_2@16^\circ C$ from all three years (346 μatm), these increases correspond to 7.5% and 1.0% increases, which are proportional to the calculated increase in the North Sea DIC inventory. This agreement implies that the surface expression of $pCO_2@16^\circ C$ is, to a large extent, representative of the entire water column, which, due to the shallow depths of the majority of the North Sea is not surprising. Similar to the distribution of DIC increase, the majority of the increase in $pCO_2@16^\circ C$ occurs in the northern North Sea, namely, where the main inflow site is for North Atlantic water. In the north ($>56^\circ N$) the average surface increase from 2001

Figure 4. Distribution of temperature-normalized (16°C) pCO₂ in surface waters. (a) in 2001, (b) 2005, and (c) 2008.

to 2005 is 44 μatm , and from 2005 to 2008 the increase is 2 μatm . The southern North Sea shows much more stable increases, of 22 μatm and 18 μatm . At this time of year in the northern North Sea, pCO_2 without the effect of temperature is predominantly controlled by biology (Prowe et al., 2009). Using this parameter $\text{pCO}_2@16^\circ\text{C}$ to investigate the differences in production between the three years would indicate a drop in primary productivity from 2001 to 2005 and 2008. However, the AOU in subsurface waters in the northern North Sea show comparable values between all three years (36.4 $\mu\text{mol kg}^{-1}$ in 2001, 30.1 $\mu\text{mol kg}^{-1}$ in 2005, and 31.3 $\mu\text{mol kg}^{-1}$ in 2008), indicating that net community production (NCP) was similar.

5. Discussion

Despite the similar fundamental patterns observed in 2001, 2005 and 2008, distinct differences occurred as a consequence of different DIC mixing patterns and proportions. In 2008, the year with the most positive NAO index (+2.1), the most pronounced front between the two mixing regimes occurs, where North Atlantic and German Bight waters were on the southern side and a mix of North Atlantic and Baltic Sea waters were on the northern side. This is caused by the fact that both the inflows of North Atlantic [Winther and Johannessen, 2006] and Baltic Sea [Hordoir and Meier, 2010] water into the North Sea are strongest under NAO+ conditions due to stronger westerly winds, strengthening the anti-clockwise circulation [Lenhart et al., 2004; Winther and Johannessen, 2006]. There is subsequently an increased flow from east to west along the isoclines at 50 m, (the Dooley current [Dooley, 1974]), in addition to increased flow down the west coast of the UK. When these inflows weaken during neutral (2005) or NAO- (2001) phases, there is a less pronounced mixing pattern and the contrast between the two regimes is diminished with more mixing occurring in the eastern central North Sea. The front between the north and south is thus less distinct or vanished, as for example, visible in the greater presence of Baltic Sea water (Figure 2) or in the distribution of A_T (Figure 1), which is unaffected by the anthropogenic CO_2 perturbation, in contrast to the remaining CO_2 system parameters.

The biogeochemical divide along the 50 m contour, separating the northern and southern North Sea, is a well-documented feature in CO_2 distributions [Thomas et al., 2004; Bozec et al., 2005; Prowe et al., 2009; Omar et al., 2010], however here, the manifestation of this divide is shown to be strongly influenced by the NAO. The observed mixing behavior has

profound implications for the distribution of pH in the North Sea (Figure 1 (c-e)). The two aforementioned mixing regimes lead to a higher pH in the stratified northern region, where Baltic Sea and North Atlantic inflows mix, and a lower, more acidic pH, in the shallower southern region. When these inflows weaken during NAO- years, evidently more thorough mixing between these regions occurs and the pH histogram reveals a more transitional pattern.

In addition to NAO driven changes in mixing ratios and rates, the North Sea CO₂ system is further affected by the biogeochemical properties of its composing water masses. This applies especially to the DIC concentrations of the inflowing North Atlantic Ocean waters, which have demonstrated substantial variability during the recent decade [Watson *et al.*, 2009; Thomas *et al.*, 2008a; Schuster and Watson, 2007]. The northern North Sea CO₂ system shows a substantial increase in DIC and temperature-normalized pCO₂ and decrease in pH between 2001 and 2005 (Figures 1 and 3) in comparison to that observed from 2005 to 2008. The concomitant change in salinity with the change in DIC throughout the water column reveals that the increase is water mass driven. Otto *et al.* [1990] state that changes in salinity in the North Sea stem from either changes in the salinity of inflowing water or changes in runoff. A shift in the salinity-DIC mixing diagram confirms that the DIC concentrations in the North Atlantic end member have increased dramatically from 2001 to 2005, which we propose is a delayed response to NAO driven changes in the North Atlantic [Thomas *et al.*, 2008]. This accelerated the decrease in pH and increase in pCO₂ of the North Sea beyond that anticipated from the rise of atmospheric CO₂ concentrations alone [Thomas *et al.*, 2007]. The DIC and salinity changes between 2005 and 2008 also demonstrated a significant correlation, but were an order of magnitude smaller thus much less pronounced, yielding similar end-member DIC concentrations for 2005 and 2008, analogous to the variable behavior observed in surface pCO₂ in the North Atlantic Ocean [Schuster *et al.*, 2009].

The same pattern was less substantial in the A_T-salinity mixing line. As the increase in DIC observed in the North Atlantic, and subsequently the North Sea, is driven by air-sea pCO₂ exchange, there is no concomitant change in A_T with DIC. However, there is still some variation in the A_T-salinity mixing lines, which could be associated with the noted change in salinity [Thomas *et al.*, 2008a]. The NAO also exerts large influence over precipitation patterns over Europe so that NAO+ leads to drier conditions across Europe but wetter conditions over Scandinavia [Hurrell and Loon, 1997]. It follows that in 2008 we would expect more rainfall and runoff in the northern area of the Baltic drainage basin, which is

associated with granite rocks and has lower A_T values compared to the south [Hjalmarsson *et al.*, 2008]. This would lead to lower A_T in 2008 compared to 2001, which is consistent with our computed A_T end members (Figure 3(b)). These changes in precipitation patterns over Europe and thus riverine runoff into the North Sea may additionally alter salinity and DIC patterns in the southern North Sea, where the majority of riverine input enters the North Sea. However, the riverine contribution represents just 0.5% of the water budget and 0.7% of the carbon budget in the North Sea [Thomas *et al.*, 2005a], which is insufficient to cause the change recorded in DIC or $p\text{CO}_2$, although it may have contributed to the observed variability.

The northern North Sea is sufficiently deep to develop a summer thermocline, thus facilitating phytoplankton blooms during the productive period, which are maintained in the surface mixed layer. Using the maximum water column value of a representative northern station of the Brunt-Väisälä frequency as an indicator of the mixed layer depth, we observe a

Figure 5. Stratification at 57°N, 2.25°E. (a) Vertical profiles of density and temperature for 2001 (blue), 2005 (green) and 2008 (red). (b) Brunt-Väisälä frequency squared profile for 2001 (blue), 2005 (green) and 2008 (red).

very stable, but shallower stratification with a surface mixed layer of approximately 30m in 2001 compared to 40m in 2005 (Figure 5). Since the residence time of the waters in the North Sea is of less than one year, there is no accumulation of metabolic DIC (previous years primary production has no effect on the current state of the North Sea). If the NCP were the same, as it was indicated in our datasets by AOU, a change in mixed-layer depth (MLD) would impact the observed $p\text{CO}_2$. While the biological $p\text{CO}_2$ drawdown was on the order of 300-330 μatm in 2001 [Thomas *et al.*, 2005b], a similar NCP would have caused a $p\text{CO}_2$ drawdown of 200-250 μatm in 2005, characterized by a mixed layer depth of 40m. This would lead to a difference of 50-130 μatm between the two years, which is in line with the observed increase of 51 μatm of temperature-normalized $p\text{CO}_2$ (Figure 4) in the northern North Sea. Taking the observed salinity change into account, such an increase would correspond to a pH decrease of 0.056.

Kühn *et al.*, [2010] have modeled a greater CO_2 sink in the northern North Sea during years of NAO- (2001) compared to years of NAO+, which they attributed to weaker stratification facilitating greater upward transport of nutrients. The highest pH values and lowest $p\text{CO}_2$ values recorded are observed in the northern North Sea during years of NAO-, however we cannot ascribe this to weaker stratification. The weaker stratification in 2005, associated with cooler temperatures, demonstrates that the expression of pH and CO_2 can be exaggerated or masked by physical conditions within the North Sea. The variability of the mixed layer depth in the North Sea is controlled by a combination of temperature and NAO [Lenhart *et al.*, 2004] and we propose the latter affects it through two possible processes. Firstly, a stronger North Atlantic inflow weakens the thermocline in years of neutral and positive NAO, leading to less stable stratification as found in 2005 and 2008. Alternatively, weaker winds may allow the thermocline to rise during more negative NAO conditions. In 2008 a stronger warming of the surface waters resulted in a more stable water column with a shallower mixed layer. This situation enhanced the NCP effect on the surface layer $p\text{CO}_2$. Simultaneously the warmer waters experienced in 2008 raised the $p\text{CO}_2$, eventually leading to comparable $p\text{CO}_2$ conditions in 2005 and 2008, with 2008 showing the warmer and shallower surface layer.

In summary our results indicate that under conditions of NAO+, as in 2008, the North Sea shelf pump is more efficient than under NAO- due to increased rates of Atlantic and Baltic inflow into the North Sea and a strengthened anti-clockwise circulation. The strengthened biogeochemical divide between the northern and southern North Sea means that more carbon is exported from the northern North Sea out of the Norwegian Trench without coming into

contact with the atmosphere, which limits subsequent out gassing of remineralized CO₂ making the shelf pump more effective. When NAO+ occurs in conjunction with a year of higher SST, shoaling of the thermocline allows intense areas of primary production to develop. This causes lower pCO₂ and higher pH in surface waters of the northern North Sea, however, this is not shown to have any effect on total carbon uptake. In addition, any changes to the biogeochemical content or quantity of the source water masses contributing to the North Sea can intensify or diminish these expressions.

Chapter 5

Direct observations of diel biological CO₂ fixation on the Scotian Shelf, northwestern Atlantic Ocean

Helmuth Thomas, William Burt, Susanne Craig, Blair J. W. Greenan, Gerhard J. Herndl, Simon Higginson, Lesley Salt, Elizabeth H. Shadwick, and Jorge Urrego-Blanco

Abstract

Much of the variability in the surface ocean's carbon cycle can be attributed to the availability of sunlight, triggering surface heat flux and photosynthesis, which in turn regulate the biogeochemical cycling of carbon over a wide range of time scales. The critical processes of this carbon cycle regulation, occurring at time scales of a day or less, however, have undergone few investigations, most of which have been limited to time spans of several days to months. Optical methods have helped to infer short-term biological variability, but complementing investigations of the oceanic CO₂ system are lacking. We employ high-frequency CO₂ and optical observations covering the full seasonal cycle on the Scotian Shelf, northwestern Atlantic Ocean, in order to unravel diel periodicity of the surface ocean carbon cycle and its effects on annual budgets. Significant diel periodicity in the surface CO₂ system occurs only if the water column is sufficiently stable as observed during seasonal warming. During that time biological CO₂ drawdown, or net community production (NCP), is delayed for several hours relative to the onset of photosynthetically available radiation (PAR), due to diel cycles in chlorophyll *a* concentration and to grazing. In summer NCP decreases by more than 90%, coinciding with the seasonal minimum of the mixed layer depth, and resulting in the disappearance of the diel CO₂ periodicity in the surface waters.

1 Introduction

Shelf and marginal seas play a crucial role in the global carbon cycle as they link terrestrial, marine and atmospheric compartments (Ciais et al., 2008; Thomas et al., 2008; Chen and Borges, 2009). As a consequence of their role as an integral link between the compartments, the spatial and temporal variability of the carbon cycle in marginal seas is generally higher than in open ocean environments (Thomas and Schneider, 1999; Schiettecatte et al., 2006; Chen and Borges, 2009; Omar et al., 2010). In addition to natural drivers, anthropogenic processes perturbing natural cycles in each of the carbon cycle compartments affect variability in shelf and marginal seas. Examples of such perturbations include eutrophication, ocean acidification and atmospheric nitrogen deposition (Doney et al., 2007; Thomas et al., 2009; Borges and Gypens, 2010; Cai et al., 2011).

Physical, biological and chemical processes govern the variability of the carbon cycle and the air-sea exchange of CO₂. Although these processes are evident at many temporal and spatial scales, they interact at high frequency local scales, eventually yielding diurnal, seasonal and longer-term periodicity. Our understanding of the monthly to seasonal variability in the carbon cycle in several shelf and marginal seas has improved, in particular with respect to attaining full annual observational coverage (Chen and Borges 2009; Thomas et al., 2004, Omar et al., 2010; Shadwick et al., 2010, 2011). At shorter time scales, optical methods have helped to infer short-term biological variability (Siegel et al., 1989; Stramska and Dickey, 1992; Cullen et al., 1992; Gernez et al., 2011; Dall’Olmo et al., 2011). However, corresponding investigations of the oceanic CO₂ system are largely lacking. A few recent studies have focused on time scales of several days to months (Hood et al., 2001; Bates et al., 2001; Copin Montegut 2004; Lefevre et al., 2008; Boutin and Merlivat, 2009; Leinweber et al., 2009; Bozec et al., 2011; Lefevre and Merlivat, 2012). Investigations of processes at the rate of their occurrence in shelf and marginal seas are still sparse when it comes to full seasonal coverage (Vandemark et al., 2011).

The Scotian Shelf region is located at the eastern Canadian continental shelf at the boundary between the subpolar and subtropical gyres. This region is thus influenced by water masses of Arctic origin via the Labrador and Newfoundland Shelves, by low-salinity waters emanating from the Gulf of St. Lawrence, and by the Gulf Stream (Urrego-Blanco and Sheng, 2012). One of the dominant characteristics on the shelf is the large seasonal amplitude in sea surface temperature (SST) between subzero temperatures in winter to approximately 20°C during summer (Shadwick and Thomas, 2011)(Fig. 1). Recent studies have identified this region as a strong source for atmospheric CO₂ at the annual scale, with an intense, but brief period of CO₂ uptake during the spring bloom, which occurs at the

annual SST minimum in late March to early April (Shadwick et al., 2011a)(Fig. 1). Controls of the seasonal to interannual variability of the surface CO₂ system in the Scotian Shelf region have been inferred from satellite observations, and include the intensity of autumn and winter storms, winter nutrient levels, and the onset of post-winter water column stratification (Greenan et al., 2004, 2008; Shadwick et al., 2010). The processes controlling the variability of the carbon cycle at time scales shorter than the monthly to seasonal scale remain poorly understood, which is the case for most regions of the open oceans, as well as for shelf and marginal seas. This study sheds light on the role of high frequency processes in controlling the carbon cycle in the surface waters of the Scotian Shelf region over a complete annual cycle. In particular, we investigate the occurrence of processes with diel periodicity, how their occurrence is controlled and how they contribute to seasonal and annual patterns of the surface water CO₂ system on the Scotian Shelf.

2 Material and methods

Investigations of the carbon cycle on the Scotian Shelf were initiated in 2006, and comprise shipboard observations of the carbon cycle and complementary parameters through the entire water column, as well as deployment of a CARIOCA buoy. Sporadically, these observations were paralleled by the deployment of the SeaHorse profiler, as detailed below. In-depth descriptions of the buoy location and the corresponding sampling activities have been given in Shadwick et al. (2011a). Here, we employ observations from the CARIOCA buoy, deployed since April 2007, that records surface water pCO₂, SST, salinity, and complementary parameters at an hourly rate and at a depth of approximately 2m. Details of the CARIOCA sensor have been reported, for example, by Bates et al. (2000, 2001), Bakker et al. (2001) and Hood and Merlivat (2001). In order to avoid data gaps due to maintenance, we reconstruct an annual cycle using different years of observations (Fig. 1). We focus on three key periods of the annual cycle: firstly, winter (pre-spring bloom to spring bloom transition); secondly, late spring to early summer, i.e., the warming period; and thirdly, the autumn to winter transition (Fig. 1). Diel cycles in pCO₂ with hourly resolution were established by removing the 48-point moving average from the (hourly) observations, which is similar to the approach pursued by Leinweber et al. (2009). We corrected the in-situ pCO₂ observations (pCO_{2, obs}) for each day to the daily mean temperature (pCO_{2, temp}) of that day using the full suite of carbonate system equations via the CO2SYS program (Lewis and Wallace, 1998) with the constants by Dickson and Millero (1987). As discussed in Sect. 3, the difference between these values reveals the biologically driven change of pCO₂ (pCO_{2, bio}):

$$pCO_{2, obs} - pCO_{2, temp} = pCO_{2, bio} \quad (1)$$

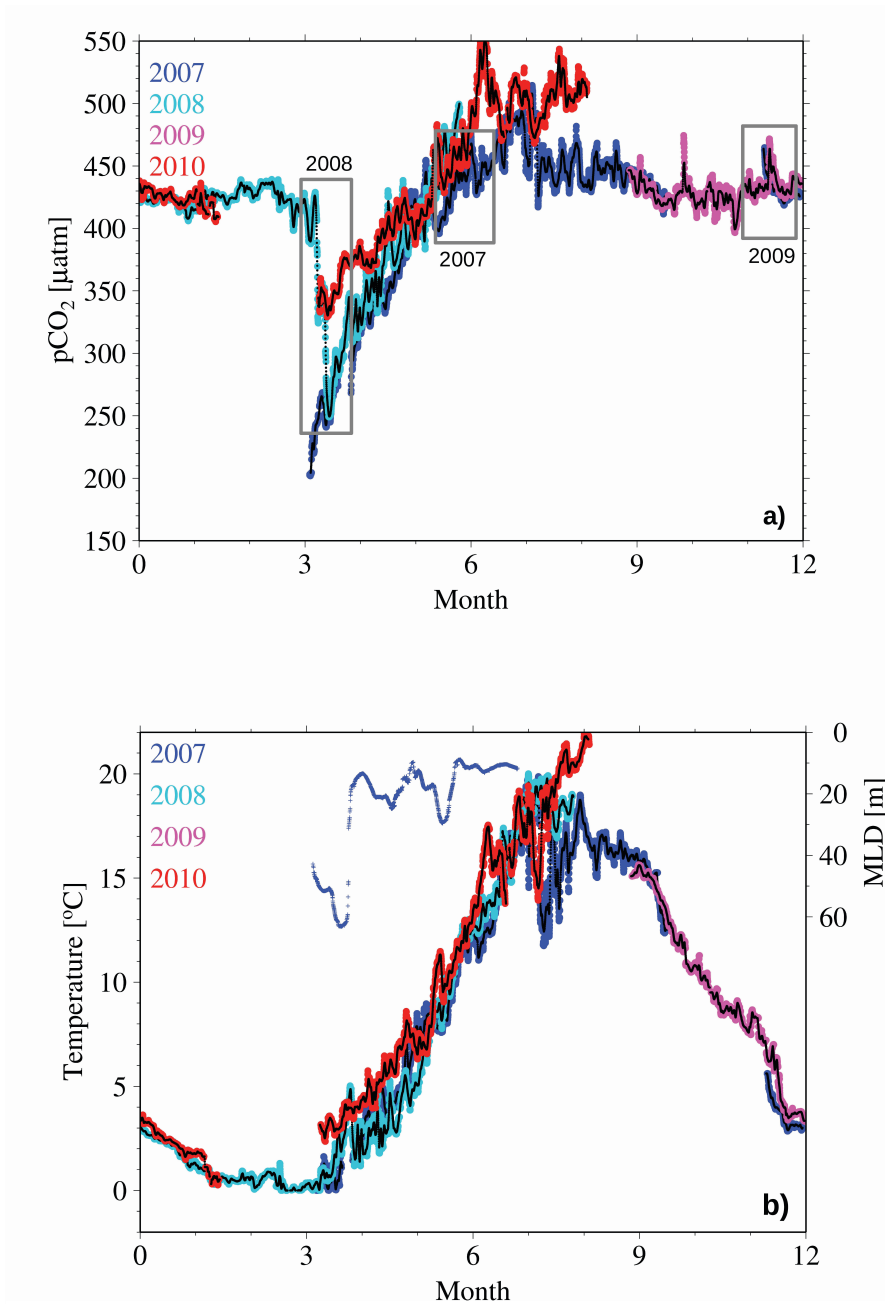

Figure 1. Composite of available pCO₂ (a) and temperature data (b) for the years 2007-2010, recorded by the CARIOCA buoy. For the further study we evaluate data from June/July 2007, April 2008 and November/December 2009 as indicated by the gray boxes in a), assuming a climatological annual cycle. The black lines indicate the 24-point moving average. In (b), the depth of the maximum of the Brunt-Väisälä frequency is shown as measure of the mixed layer depth (MLD), computed from the Seahorse data, deployed between April 2007 and July 2007.

Mean diel cycles for the spring period (days 160-200 representing the period, when surface waters warm) were computed as the corresponding 40-day average of each hour of the day (Figs. 2a, b, 4d). Under consideration of the salinity records of the CARIOCA buoy and the salinity-alkalinity relationship reported by Shadwick et al. (2011a), we computed dissolved inorganic carbon (DIC) concentrations as a function of pCO₂ and alkalinity using CO₂SYST (Lewis and Wallace, 1998) and the carbonate system constants by Dickson and Millero (1987). The integration of the biological component of the diel DIC cycles yielded the estimates of the biological rates.

In order to investigate the crucial period between spring and summer, when the waters are warming (Fig. 1), we combine the CARIOCA data with observations from the SeaHorse, an autonomous profiler (Greenan et al., 2004, 2008), which records water column profiles of temperature, salinity, photosynthetically active radiation (PAR), and downwelling irradiance ($E_d(\lambda)$) between 3-80m depth. Profiles were recorded with approximately 0.5 m vertical resolution approximately every 2 h between 4 April 2007 and 27 July 2007. The comparison of the diel temperature anomaly recorded at the sea surface by the CARIOCA buoy and the SeaHorse, respectively, shows good agreement of both instruments in timing and amplitude (Fig. 2a). The obtained diel cycle in surface temperature with an amplitude of 0.2 - 0.3°C is the result of incoming solar radiation of approximately 500 W m⁻² over 10 - 12h per day in a mixed layer depth (MLD) of 10-20m.

In an attempt to resolve the contribution of phytoplankton to NCP during the warming period, we derived chlorophyll a concentrations between 5 and 6m from profiles of SeaHorse $E_d(\lambda)$ using the model of Nahorniak et al. (2001). This depth range was chosen to be as close to the depth of the CARIOCA sensors (2m) as possible,

Figure 2. (a) Comparison of the diel temperature anomaly recorded by the CARIOCA buoy (red) and the SeaHorse profiler (blue), shown as average of the days 160-200. (b) Diel MLD anomaly, shown as average of the days 160-200, computed from the maximum of the Brunt-Väisälä frequency as measure of the MLD. (c) Correlation between the Chl α concentrations measured and modeled after Nahorniak et al. (2001).

whilst preventing the inclusion of noisy E_d data due to surface light wave focusing. The model required that the attenuation of E_d is calculated at three wavelengths (412, 443, 555 nm) over a depth interval (5 – 6m). Since the sensor wavelengths (379.3, 442.9, and 491 nm) did not exactly match the wavelengths required by the model, $E_d(\lambda)$ was first interpolated to model wavelengths. Modelled chlorophyll α (Chl_{mod} ; mg m^{-3}) at an average depth of 5.5m (i.e. halfway between 5 and 6m) was then calculated using Nahorniak et al.'s (2001) formulations that include spectral coefficients to describe the absorption properties of water, phytoplankton and coloured dissolved organic matter and assume a value of 0.8 for the average cosine of downwelling light, μ_d (dimensionless). Chl_{mod} values were compared with discrete, fluorometrically determined chlorophyll α values obtained at the same time and depth from ship-based water samples (Fig. 2c), and R^2 , root mean square error (RMSE; mg m^{-3}) and bias (mg m^{-3}) values of 0.92, 4.31 mg m^{-3} , and -1.76 mg m^{-3} ($N = 8$), respectively, were obtained. These values were then grouped into periods 1-3 as described above, and averaged into time bins to give climatological values for Chl_{mod} every two hours during the hours of daylight when reliable $E_d(\lambda)$ measurements could be made, which, at this time of year and latitude corresponded to times between ~06:00-16:00 local time.

3 Results and discussion

The spectral analysis of the buoy data (Fig. 3a, b) revealed a 24-h periodicity for the parameters pCO_2 and SST that occurs only when the waters are warming, i.e. between April and late August. Both pCO_2 and SST also showed significant coherent patterns during this time of the year (Fig. 3b, bottom panel, Fig. 3c) and are the focus of this paper. Outside of this period, periodicity and significant coherence were only observed, if detected, at longer time scales (several days), which mirrors the typical frequency of winter storms in the region (Fig. 3c). Other parameters, such as salinity, do not show significant 24-h periodicity, which means that tidal, lateral and other effects are either not identifiable, or act on timescales longer than 24 h. Such processes would be captured by the 48-point moving average, and do not influence the diel cycles. We also verified the potential role of daily cycles in MLD, which could lead to an intrusion of CO_2 -rich water into the surface layer, if the MLD deepens. Boutin and Merlivat (2009) suggested that this process is an important driver of the diel pCO_2 anomaly. Leinweber et al. (2009), however, suggest that the deepening of the MLD is of minor importance due to the absence of a strong vertical gradient in DIC at their study site. The computation of the diel MLD anomaly for our location did not reveal a significant diel pattern, with variability, on the order of a few tens of centimeters (Fig. 2b), given a MLD of 10-20m. We therefore consider the influence of

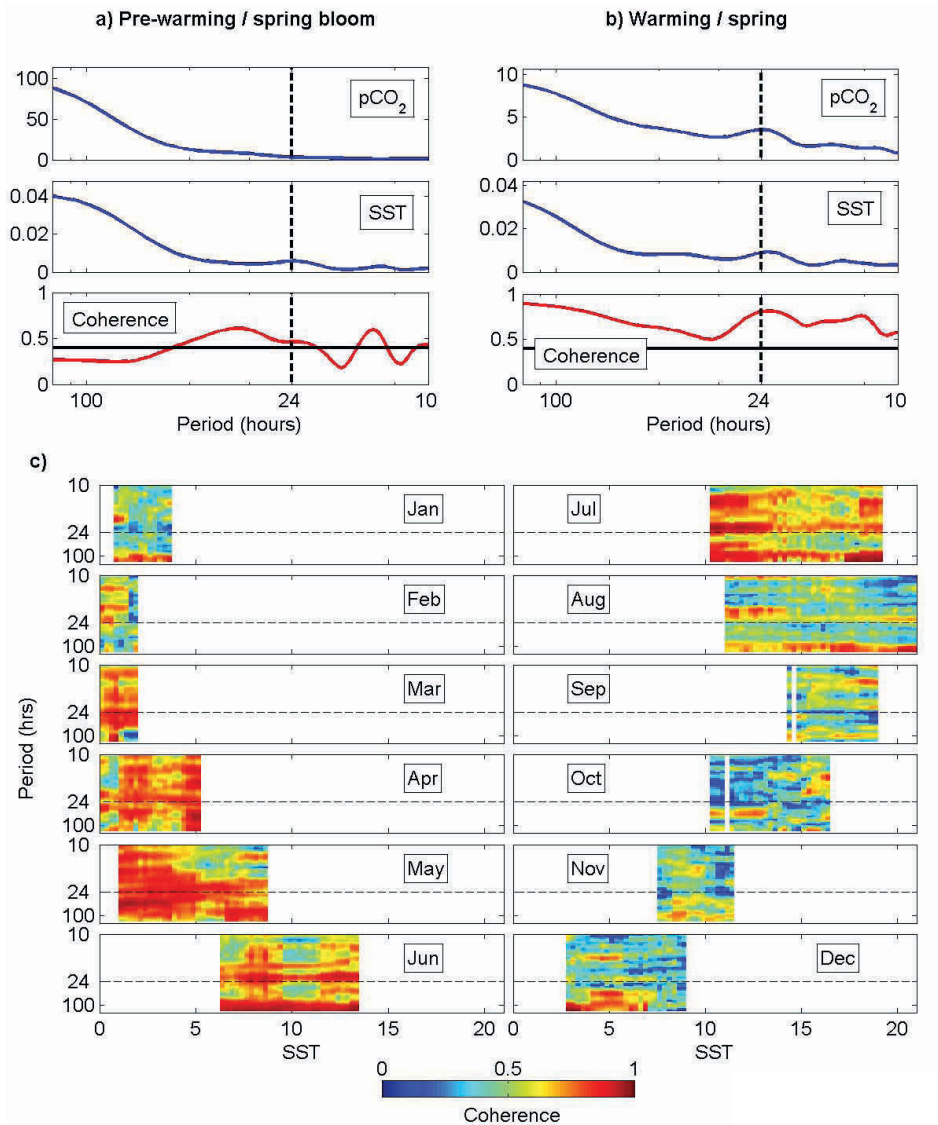

Figure 3. Spectral analysis of $p\text{CO}_2$ and SST data from the CARIOCA buoy. Power spectra of $p\text{CO}_2$ and SST and their coherence are shown for two periods: a) the pre-warming/spring bloom period and b) the warming period (see Figure 1a gray boxes). The dashed line on each plot indicates the 24 h period, and the horizontal solid line on the coherence plots shows the 5% significance level based on the degrees of freedom of the cross-spectral estimators. The coherence between $p\text{CO}_2$ and SST is plotted as a function of SST in monthly composites (c), illustrating the temporal evolution of the coherence. The color scale indicates the level of coherence between $p\text{CO}_2$ and SST, and the dashed line shows the 24 h period. High coherence at the 24 h period occurs only during the period when the water is warming.

temperature-driven diel variability in MLD as negligible in our case. The CO₂ air-sea fluxes play a very minor role in the surface layer DIC concentrations at the 24h timescale, such that the feedback between pCO₂ and CO₂ air-sea fluxes is negligible in our study.

Surface heat fluxes cause variability in SST at diel and seasonal time scales (Umoh and Thompson, 1994), which in turn drive some of the observed variability of the pCO₂, primarily because of the temperature dependence of the Henry constant. We corrected the observed pCO₂ data (pCO_{2, obs}) to a daily mean temperature to give pCO_{2, temp}. The difference between pCO_{2, obs} and pCO_{2, temp} yielded pCO₂ data that were governed by processes other than temperature within a 24 h period. Since we did not detect processes other than SST variability acting on the 24 h period, the remaining pCO₂ variability was ascribed to biological activity (pCO_{2, bio}, Eq. 1). The daily and diel variability of the pCO_{2, obs} and pCO_{2, bio} for three periods of the year is shown in Fig. 4. In the winter period (days 80-95, Fig. 4a), the amplitude of the diel oscillation was small and the pCO₂ relatively constant. With the onset of the spring bloom, at approximately day 95 (see also Shadwick et al., 2011a, their Figs. 4 and 16), the diel amplitude drastically increased (Fig. 4a). Throughout both of these periods, pCO_{2, obs} and pCO_{2, bio} were in phase and tracked each other closely indicating that temperature was not the main driver for the short-term variability during this time of the year. Similarly, in the autumn to winter (Fig. 4b) transition, pCO_{2, obs} and pCO_{2, bio} again revealed in-phase patterns, though with a higher amplitude in autumn (days 305-345) than in winter (days 80-95), which can be ascribed to deepening of the mixed layer and an intrusion of high pCO₂ subsurface waters into the surface mixed layer (Shadwick et al., 2011a). Between the days 160-200 (end of June until end of July), i.e. later in the season of surface water warming, the amplitude of the diel oscillation was reduced compared to that observed during the spring bloom (Fig. 4a-c). More importantly, a phase shift was detectable between pCO_{2, obs} and pCO_{2, bio}, with the latter occurring approximately 3h earlier than the pCO_{2, obs} (Fig. 4c, d). We postulate that the cause for this phase shift might be diel cycles in biological activity. Such diel cycles were only visible, when the water column was sufficiently stable, such as during thermal stratification (Fig. 1b; Shadwick et al., 2011a, their Fig. 9). Outside the warming period, several processes have the potential to obscure or prevent diel signals or their detection: For example, during the autumn and winter periods, thermal stratification breaks down due to cooling air temperatures and increased wind-driven mixing resulting in a deepening of the mixed layer and greatly decreased photosynthetic activity, meaning that the diel cycles easily detectable during the warming period are difficult to detect or are completely absent in autumn and winter.

We can consider the diel cycle of pCO₂ as a composite of a temperature-driven component, which follows the diel cycle of SST (Fig. 4d), and a biologically driven component,

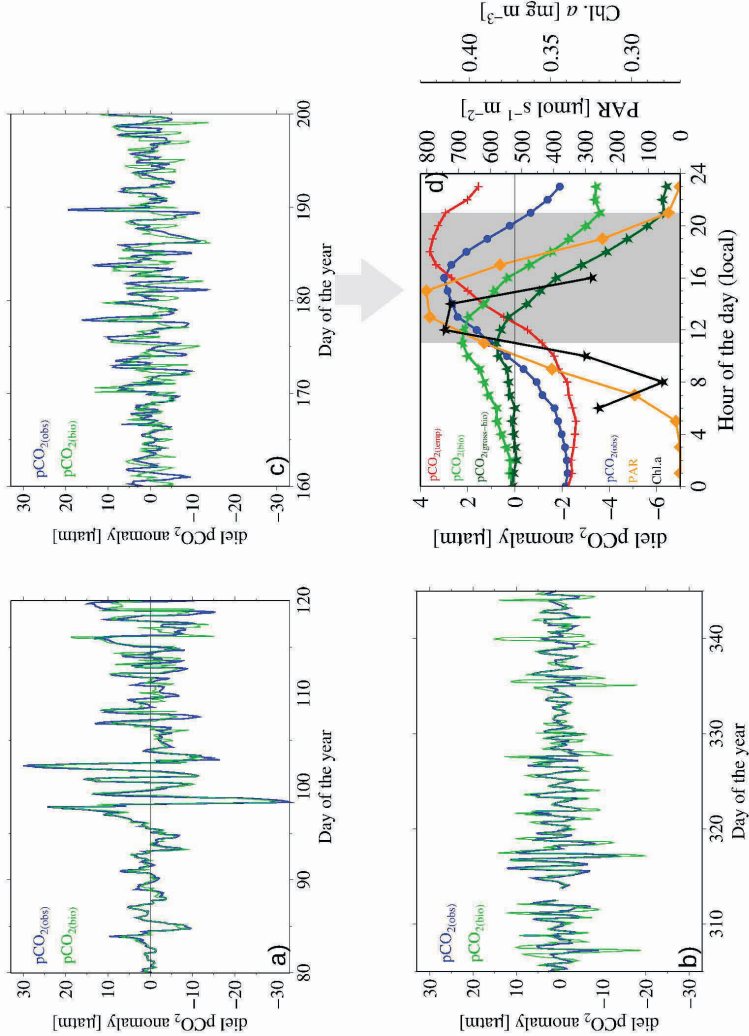

Figure 4. Diel anomalies and daily cycles of observed pCO₂, biologically controlled pCO₂, PAR, and Chl. a. Shows diel anomalies of pCO_{2,obs} (blue) and pCO_{2,bio} (green) for three periods of the year (a–c) as depicted in Fig. 1. Note the phase shift in the warming period (c, d), while outside the warming period (a, b) both parameters show the same timing (i.e., they are independent). Average diel anomalies or daily cycles compiled for the 40-day period from days 160–200 (see Fig. 1) observed pCO₂ (pCO_{2,obs}, blue), biologically controlled pCO₂ (pCO_{2,bio}, green), temperature-only controlled pCO₂ (pCO_{2,temp}, red), pCO_{2,bio} corrected for respiratory activity (pCO_{2,gross-bio}, dark green) and photosynthetic active radiation (PAR, orange). Chlorophyll a (Chl. a, black) is shown for the hours (6:00h–16:00h), when reliable E_d(λ) measurements can be made by the Seahorse. The gray-shaded box indicates the period when net carbon fixation occurs. The respiration rate has been computed from the slope of the pCO_{2,bio} during night time conditions and production rates have been computed from the slopes of pCO_{2,bio} and pCO_{2,gross-bio} during daytime (gray-shaded area).

controlled by the balance of production and respiration of organic matter. The diel biological cycle obtained here can be considered a net biological signal, which shows an increase of the $p\text{CO}_2_{\text{bio}}$, i.e. net respiration, beginning in the evening (approx. 21:00h) and ending in the morning hours (10:00h-11:00h), when net community production (NCP) begins to exceed community respiration. NCP, indicated by a negative gradient in the $p\text{CO}_2$ anomaly (Fig. 4d), dominates the system until dusk. Subtracting the respiration signal, computed from the slope of the $p\text{CO}_{2(\text{bio})}$ during nighttime conditions, allows us to estimate the diurnal cycle of gross primary production (GPP). The corresponding respiration rate, assumed to be constant throughout the day, is estimated to be $0.05 \mu\text{mol C (L h)}^{-1}$; the rates of NCP and GPP are $0.26 \mu\text{mol C (L h)}^{-1}$ and $0.31 \mu\text{mol C (L h)}^{-1}$, respectively, both lasting approximately 10 h per day. This compares well with the GPP estimates given by Forget et al. (2007, their Table 2), which, when combined with an assumed 30m in MLD, yield GPP rates of $13 \mu\text{mol C (1 d)}^{-1}$. It must be noted, however, that their station is somewhat further offshore at the shelf break than the mooring location of the CARIOCA buoy and the SeaHorse. Somewhat more difficult to compare are the daily production rates reported by Boutin and Merlivat (2009), which range between $1.8 \mu\text{mol C (1 d)}^{-1}$ and $4.8 \mu\text{mol C (1 d)}^{-1}$. While their method of estimating NCP is similar to our approach, the data were obtained in the Southern Ocean at comparable latitude, but from a drifting instrument.

The onset of the net photosynthetic CO_2 drawdown occurred approximately 4-5 h after sunrise, near the period maximum of PAR (Fig. 4d) - a phenomenon that has been frequently documented but surprisingly has rarely been discussed or addressed in detail. Stramska and Dickey (1992), Siegel et al. (1989) and Gernez et al. (2011) report a phase shift of several hours between the onset of PAR and maximum values of either the beam attenuation coefficient (c_p) or dissolved oxygen (O_2) concentrations. The latter two are mirroring the build up of photosynthetic organic matter and reveal phasing throughout the diurnal cycle, which is comparable to the phasing of $p\text{CO}_{2_{\text{bio}}}$. Bozec et al. (2011, their Fig. 5) also show a similar phase shift between dissolved O_2 and $p\text{CO}_2$, relative to PAR. They conclude, however, that $p\text{CO}_2$ and PAR are out of phase by 180 degrees and O_2 is in phase with PAR. Leinweber et al. (2009) report similar but shorter time lags between their $p\text{CO}_2$ parameters, which tend to reveal stronger diel amplitudes than we observed. Overall, it appears that the temperature control of their system is more pronounced than on the Scotian Shelf, as evident from the higher diel temperature amplitude of 4°C in the Santa Monica Bay (Leinweber et al., 2009), compared to 0.2°C on the Scotian Shelf (Fig. 2a). Lefevre and Merlivat (2012) report for the tropical eastern Atlantic a time lag between PAR and SST; however, the relationship with chemical parameters (DIC, oxygen) appears complex and variable, likely because of physical processes. In summary, it appears that there is sufficient evidence in the literature to suggest that the signal of net biological carbon fixation in the water column, as

revealed by pCO₂, O₂ or beam attenuation measurements, is detectable at or around peak PAR, which is the ultimate energy source for the biological carbon fixation.

In order to determine whether this reported periodicity in metrics of phytoplankton photosynthetic activity occurred at our study site, we binned averaged Chl_{mod} over the 40-day warming period (days 160-200). This revealed a diel cycle with a difference of approximately 30% (0.13 mg Chl α m⁻³) between minimum and maximum values, with the lowest values corresponding to low PAR levels during early morning and late afternoon, and maximum values to peak PAR at around noon (Fig. 4d). Please note that the daily Chl_{mod} excursion is small compared to the RMSE of 4.31 mg m⁻³ (Fig. 2c), indicating that quantitative interpretation of Chl_{mod} results should be made with caution. However, even if not a truly quantitative estimate of Chl α , the diel, i.e. relative Chl_{mod} pattern, observed at our study site is significant and, furthermore, is very similar to those observed in other studies of optical signals that have been interpreted as the combined effects of processes including daily primary production, phytoplankton sinking, and zooplankton grazing (Gardner et al., 1993; Marra, 1997; Stramska and Dickey, 1992; Gernez et al., 2011). When compared with the pCO₂ diel cycles, it was observed that the onset of net CO₂ drawdown, indicated by the change in slope of pCO_{2, bio} from positive to negative, coincided with the time of the maximum Chl_{mod} values (Fig. 4d). In other words, our data suggest that a threshold Chl α concentration must first be attained during the growth phase before the system achieves net CO₂ drawdown. Others have also reported diel signals in either Chl *a* or photosynthetic parameters (Cullen et al., 1992; Bruyant et al., 2005), with peak values around noon. It should also be noted that photoinhibition may depress photosynthetic rate at high irradiances, especially around noon, potentially further modulating the exact occurrence of net CO₂ drawdown with respect to PAR levels.

Another process that may have contributed to the patterns in Chl_{mod} is phytoplankton diel vertical migration, whereby cells migrate to well lit surface waters during daylight hours and to deeper, nutrient rich waters at night. At this time of year (June-July), the phytoplankton community was dominated by flagellates (Harrison et al., 2008), which are well known to exhibit diel vertical migration patterns (Eppley et al., 1968; MacIntyre et al., 1997; Hall and Paerl, 2011), making it likely that this process contributed, at least in part, to both the accumulation of biomass during daylight hours and to the lag time between PAR and NCP, when the flagellates first have to move upward to reach the well lit surface during the early morning hours.

Both our results and those reported in the literature are consistent with the notion of a phase shift between the onset of PAR at dawn and of net carbon fixation at

approximately solar noon. Meso- and microzooplankton, which are active during nighttime, might still exert grazing pressure on phytoplankton during the early morning hours and thereby keep the abundance of phytoplankton low during the initial hours of daylight (Siegel et al. 1989). In addition to grazing effects, the diurnal variability in phytoplankton photosynthetic activity itself also contributes to delaying net carbon fixation until PAR has reached approximately maximum values as discussed above. Furthermore, in order to detect net carbon fixation as a change in the $p\text{CO}_2$ (or O_2 concentrations) in the water column, primary producers have to compensate for the respiratory activity of the heterotrophs, which in turn might exhibit relatively constant activity rates throughout the diel cycle (Cullen et al., 1992; Gernez et al., 2011). Based on our analysis, we suggest that grazing and the dependence of the photosynthetic rate on PAR lead to a net-autotrophic system just before, or at, maximum PAR values (Fig. 4d). As mentioned earlier, in our study we were not able to identify any diurnal variability in the water column structure, i.e. in strength and depth of stratification, which might have provoked the phase shift between PAR and $p\text{CO}_{2,\text{bio}}$.

We have revealed the seasonal dynamics of NCP by integrating the hourly $p\text{CO}_{2,\text{bio}}$ values (Fig. 5), yielding the biologically driven DIC concentration change, or under consideration of the MLD, the NCP inventory. The maximum value of NCP is 3.4 mol C m^{-2} or $271 \text{ } \mu\text{mol C L}^{-1}$, which is with respect to temporal evolution and magnitude of NCP similar to the results reported by Shadwick et al. (2011a), thus underpinning the importance of biological processes in the surface layer DIC variability. The integration of hourly values provides further evidence for the ongoing biological CO_2 fixation after the spring bloom as a significant contributor to annual CO_2 fixation (Shadwick et al., 2011a, b). Of particular interest is the observation that the carbon fixation rate, i.e. the DIC uptake rate by phytoplankton, is fairly constant from the onset of the spring bloom (approx. day 100) to approximately day 180, with DIC uptake rates of approximately $2.5 \text{ } \mu\text{mol C (L d)}^{-1}$, corresponding to a NCP rate of $0.26 \text{ } \mu\text{mol C (L h)}^{-1}$, assuming a 10-hour photoperiod per day (Fig. 4d). Again, this compares well with the GPP rates of $1\text{--}3 \text{ } \mu\text{mol C (L d)}^{-1}$ as reported

Figure 5. Annual cycle of biological DIC uptake. We show the annual cycle of biological DIC uptake, integrated from hourly values, i.e. accumulated diel changes. The mixed layer inventory of biological DIC uptake was obtained by dividing the biological DIC concentration change by the MLD as reported by Shadwick et al. (2011a). The production rates were computed from the slopes of the DIC uptake.

by Forget et al. (2007) for this period. Charette et al. (2001) reported ¹⁴C-based GPP rates, determined for the area in September 1997, of 0.9-13 $\mu\text{mol C (L d)}^{-1}$, assuming a 30m MLD. These GPP rates were given without estimates of water column respiration, hindering a direct comparison to our data. The production rate decreases to about 0.1 $\mu\text{mol C (L d)}^{-1}$ (Fig. 5), when the mixed layer depth reaches its minimum. Thereafter, a combination of dramatically reduced availability of nutrients and photoinhibition of photosynthesis reduces NCP substantially in autumn.

4 Conclusions

In summary, we observed a statistically significant diurnal periodicity of the CO₂ system in surface waters only during the period when the water is warming. The corresponding increase in water column stability during warming facilitates the appearance of the diurnal cycle. The unravelled diurnal cycles of the surface pCO₂ reveal that net photosynthetic carbon fixation, i.e. NCP, begins approximately 4-5 h after onset of PAR. Grazing and transitional metabolic rates are likely the responsible processes for this phase shift, eventually allowing the ecosystem to be autotrophic for approximately 10 h out of 16 h of daylight during spring and early summer.

Chapter 6

Rapid acidification of mode and intermediate waters in the southwest Atlantic Ocean

Lesley A. Salt, Steven M.A.C. van Heuven, Maaïke E. Claus, Elizabeth M. Jones,
and Hein J.W. de Baar.

Abstract

Observations along the southwest Atlantic WOCE A17 line made during the Dutch GEOTRACES-NL program (2010-11) were compared with historical data from 1994 to quantify the changes in the anthropogenic component of the total pool of dissolved inorganic carbon (ΔC_{ant}). Application of the extended Multi Linear Regression (eMLR) method shows that the ΔC_{ant} from 1994 to 2011 has largely remained confined to the upper 1000 dbar. The greatest changes occurred in the upper 200 dbar in the SubAntarctic Zone (SAZ), where a maximum increase of $37 \mu\text{mol kg}^{-1}$ is found. South Atlantic Central Water (SACW) experienced the highest rate of increase in C_{ant} , at $0.99 \pm 0.14 \mu\text{mol kg}^{-1} \text{ y}^{-1}$, resulting in a rate of decrease in pH of -0.0016 yr^{-1} . The highest rates of acidification relative to ΔC_{ant} , however, were found in SubAntarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW). The low buffering capacity of SAMW and AAIW combined with their relatively high rates of C_{ant} increase of $0.53 \pm 0.11 \mu\text{mol kg}^{-1} \text{ y}^{-1}$ and $0.36 \pm 0.06 \mu\text{mol kg}^{-1} \text{ y}^{-1}$, respectively, has, and will continue to cause rapid acidification in the SAZ and simultaneously reduce the chemical buffering capacity of this significant CO_2 sink.

1 Introduction

The Atlantic Ocean contains the largest store of anthropogenic carbon (C_{ant}) of all the world's oceans, accounting for approximately 38% of the total C_{ant} inventory (Sabine et al., 2004). Within the Atlantic, the North Atlantic is currently responsible for the majority of the uptake of C_{ant} (Levine et al., 2011), due to the formation of North Atlantic Deep Water (NADW). However, a recent Atlantic basin inventory analysis indicates that in the past decade the South Atlantic has been more effective at sequestering C_{ant} (Wanninkhof et al., 2010) than the North Atlantic. These authors calculated a rate of increase of the North Atlantic inventory of $1.9 \text{ Pg C decade}^{-1}$, whereas the South Atlantic inventory grew at a rate of $3.0 \text{ Pg C decade}^{-1}$. Calculations by Ríos et al. (2012) indicate that the southwestern Atlantic Ocean dominates the South Atlantic sink of C_{ant} , with a storage rate of $0.25 \pm 0.035 \text{ Pg C decade}^{-1}$. Quantifying the exact rate of increase in anthropogenic carbon in ocean waters is inherently problematic due to the highly variable nature of dissolved inorganic carbon (DIC) within the ocean and the relatively small fraction that the anthropogenic component represents ($\sim 3\%$; Ríos et al., 2010). In the past decade a number of methods for calculating the increase in C_{ant} (ΔC_{ant}) between reoccupations of ocean transects have been developed (e.g. TrOCA, φC_T^0 , eMLR). Despite the differing approaches and assumptions, there is overall coherence in the determinations of the C_{ant} in the world's oceans (Lee et al., 2003; Peng et al., 2003; Álvarez et al., 2009; Wanninkhof et al., 2010).

The southwest Atlantic has been occupied several times over the past 20 years and several techniques to determine C_{ant} have been applied to the WOCE '94 A17 transect by Ríos et al. (2010). All methods confirmed maximum C_{ant} concentrations in South Atlantic Central Water (SACW), however, south of 40°S discrepancies between the methods (ΔC^* (Gruber et al., 1996), Tracer combining Oxygen, inorganic Carbon and total Alkalinity (TrOCA) (Touratier et al., 2007), φC_T^0 (Vázquez-Rodríguez et al., 2009a), Transit Time Distributions (TTD) (Waugh et al., 2006)) is significant. Generally, the TrOCA method provided the highest estimate, followed by φC_T^0 and TTD, however all show great conformity in latitudinal behavior.

The presence of the western boundary current in the South Atlantic Ocean means that the C_{ant} signal penetrates deeper and is larger in the western half of the basin compared to the eastern half (Wanninkhof et al., 2010; Ríos et al., 2010; Vázquez-Rodríguez et al., 2009). Murata et al. (2008) show that the C_{ant} signal in SubAntarctic Mode Water (SAMW) can be $\sim 7 \mu\text{mol kg}^{-1}$ higher west of 15°W compared to the east. The major pathways of C_{ant} into the South Atlantic ocean interior are by means of the formation of mode and intermediate waters (McNeil et al., 2001; Sabine et al., 2004). The SAMW is formed in the SubAntarctic Zone

(SAZ), between the Subtropical Front (STF) and subAntarctic Front (SAF), where a calculated anthropogenic CO_2 uptake of $0.07 - 0.08 \text{ PgC yr}^{-1}$ occurs (Sabine et al., 1999; McNeil et al., 2001). A total CO_2 sink of 1.1 Pg C yr^{-1} has been calculated by McNeil et al. (2007) for the SAZ, making it the largest CO_2 sink in the Southern Ocean and a significant sink for anthropogenic atmospheric CO_2 .

The increase in DIC that results from the uptake of anthropogenic CO_2 from the atmosphere leads to increasing proton, bicarbonate ion and carbon dioxide concentrations ($[\text{H}^+]$, $[\text{HCO}_3^-]$, $[\text{CO}_2]$) and decreasing carbonate concentrations ($[\text{CO}_3^{2-}]$), a process referred to as *ocean acidification*. Sabine et al. (2004) state that approximately 50% of the total amount of C_{ant} in the world's oceans resides in the upper 400 m. The associated decrease in pH has been calculated as -0.1 pH units in the surface ocean relative to pre-industrial times (Royal Society, 2005; Orr et al., 2005). In the North Atlantic Ocean acidification rates of $-0.0016 \pm 0.0001 \text{ yr}^{-1}$ and $-0.0012 \pm 0.002 \text{ yr}^{-1}$, for SubArctic Intermediate Water (SAIW) and SubPolar Mode Water (SPMW), respectively, have been reported (Vázquez-Rodríguez et al., 2012). Data from the European Time Series in the Canary Islands (ESTOC) station shows significantly higher rates of pH decrease in surface waters of $-0.0017 \pm 0.0004 \text{ yr}^{-1}$, for the time period 1995 to 2004, with notable influence from regional climatic forcing (Santana-Casiano et al., 2007). Acidification rates that deviate from the rate expected from C_{ant} increases alone have been observed in upper Labrador Sea Water (uLSW), SAIW, and eastern North Atlantic Central Water (eNACW) (Vázquez-Rodríguez et al., 2012). These variations have been attributed to a combination of climatic and biological effects. The greater sensitivity of some water masses to acidification has been well documented by González-Dávila et al. (2011) through the application of the buffering factors described by Egleston et al. (2010) and previously Frankignoulle (1994). González-Dávila et al. (2011) showed that waters originating at high latitudes are particularly sensitive to increases in the concentration of dissolved CO_2 ($[\text{CO}_2(\text{aq})]$), in particular Antarctic Intermediate Water (AAIW) and upper Circumpolar Deep Water (uCDW) due to low total alkalinity (A_T) to DIC ratios.

A number of the biological consequences of ocean acidification are related to the changes in $[\text{CO}_3^{2-}]$, and thus the concentration of calcium carbonate ($[\text{CaCO}_3]$). Carbonate and bicarbonate ions are used by marine calcifying organisms to form both varieties of calcium carbonate: aragonite (e.g. by pteropods) and calcite (e.g. by coccolithophores and foraminifera). Aragonite is the less metastable form of CaCO_3 resulting in a saturation horizon ($\Omega_{\text{Ar}}=1$) approximately 2 km shallower than that of calcite ($\Omega_{\text{Ca}}=1$) in the South Atlantic Ocean. Below these depths the respective forms of CaCO_3 are no longer present in particulate form. It follows that organisms which use aragonite are much more vulnerable to

decreases in $[\text{CO}_3^{2-}]$ driven from surface increases in $[\text{CO}_2]$ than organisms using calcite. A number of experiments have observed shell dissolution in pteropods incubated at elevated partial pressure of CO_2 (pCO_2) (Orr et al., 2005; Lischka et al., 2011) associated with a lowering of the aragonite saturation state (Ω_{Ar}). Recently similar results have been observed *in situ* in the Southern Ocean (Bednaršek et al., 2012), indicating that species are already being affected by C_{ant} accumulation.

This study examines the increase of C_{ant} in the southwest Atlantic Ocean between two occupations of the WOCE A17 line, which took place in 1994 and 2010/11. We calculate the changes in C_{ant} ($\Delta\text{C}_{\text{ant}}$) in the different water masses and subsequently examine the pH changes driven by the invasion of anthropogenic carbon between WOCE '94 A17 and GEOTRACES-NL (2010/2011). These results are furthermore put into context with regard to the differing buffering capacities of individual water masses.

2 Data and Method

2.1 Datasets

The two datasets used in this study are the results from the CO_2 survey data from the WOCE '94 A17 section (public data at: http://cdiac.ornl.gov/oceans/woce_a17c.html) and the Dutch West Atlantic GEOTRACES program, completed in 2011 (GEOTRACES-NL (2010/2011)). The respective cruise tracks and stations are shown in Fig. 1. The GEOTRACES-NL (2010/2011) section was carried out in two parts. The shown stations north of the equator were occupied in July 2010 by the Dutch RV Pelagia (expedition 64PE321, from Hamilton, Bermuda to Fortaleza, Brazil), and the southern hemisphere was sampled during March 2011 by the British RRS James Cook (JC057, from Punta Arenas, Chile to Las Palmas, Gran Canaria). The WOCE '94 A17 section was similarly carried out in austral autumn and this data has undergone rigorous quality control (Key et al., 2010). The data report is available from 'http://cdiac.ornl.gov/oceans/ndp_084/' (Ríos et al., 2005b), where an offset of $-8 \mu\text{mol kg}^{-1}$ in the A_T data has been reported and

Figure 1. Cruise tracks from both cruises with used stations (black represents the WOCE '94 A17 line, red represents the GEOTRACES-NL (2010/2011) expeditions).

corrected for in this study. For a detailed analysis of the WOCE occupation we refer the reader to Ríos et al. (2010).

2.2 GEOTRACES-NL (2010/11) measurements

2.2.1 Dissolved inorganic carbon and total alkalinity

During the GEOTRACES-NL (2010/2011) cruises, for measurements of DIC and A_T , water samples of 600 ml were collected from throughout the water column, from 24 Niskin samplers mounted onto a CTD rosette, following standard operating procedures (Dickson et al., 2007). At least two duplicate samples were collected at each station, from different parts of the profile. Samples were analyzed immediately after collection on a VINDTA 3C (Versatile INstrument for the Determination of Total Alkalinity, Marianda, Kiel) instruments, simultaneously. These systems determine DIC by coulometric titration using a coulometer (Johnson et al., 1987) and determine A_T by potentiometric titration with 0.1M hydrochloric acid (Mintrop et al., 2000). Quality control was performed through regular measurements of certified reference material (CRM, Batch #100) supplied by Dr. Andrew Dickson at Scripps Institute of Oceanography (San Diego, California). Based on the measurements performed on the CRM, DIC was measured with a precision of one standard deviation of $1.0 \mu\text{mol kg}^{-1}$ and the precision of A_T had one standard deviation of $1.1 \mu\text{mol kg}^{-1}$.

2.2.2 Ancillary parameters

Dissolved oxygen samples were collected from a minimum of three depths throughout the water column for CTD sensor calibration. The samples were collected in 120 ml borosilicate glass bottles and treated following the Winkler method (Winkler, 1888) and analyzed spectrophotometrically on a Hitachi U-1100 Spectrophotometer, following Pai et al., (1993). The precision, estimated from 123 replicates, was $\pm 0.98 \mu\text{mol l}^{-1}$.

Inorganic nutrients (PO_4 , Si(OH)_4 , NO_3) were analyzed following the methods of Grasshoff et al. (1983). In every run a control and a natural sterilized, Reference Nutrient Sample (RMNS Kanto, Japan) were measured. Precision was estimated to be ± 0.01 , 0.2 , and $0.2 \mu\text{mol l}^{-1}$ for PO_4 , Si(OH)_4 , and NO_3 , respectively. Values of salinity are reported on the practical salinity scale.

2.2.3 pH Calculations

From DIC, A_T and supplementary data (salinity, temperature, pressure, Si(OH)_4 , PO_4), the pH and pCO_2 were also calculated in-situ for both datasets using CO2_SYS (Lewis and Wallace, 1998) adapted for Matlab (van Heuven, 2011a), applying the carbonic acid

dissociation constants of Mehrbach et al. (1973), (refit by Dickson and Millero, 1987), and the KSO_4 constant of Dickson (1990). The same calculation was carried out for both the WOCE '94 A17 and GEOTRACES-NL (2010/2011) datasets with the resulting pH reported on the total pH scale.

2.3 Deepwater consistency between WOCE and GEOTRACES

In a later section, we employ the eMLR method (Friis et al., 2005) to infer ΔC_{ant} between the two cruises. The eMLR method considers various biogeochemical properties (in this case, salinity (S), DIC, NO_3 , Si(OH)_4 and apparent oxygen utilization ($\text{AOU} = [\text{O}_2]_{\text{sat}} - [\text{O}_2]_{\text{obs}}$)) and is particularly sensitive to large scale (*secular*) changes in the distributions of these properties, as well as to analytical biases in their measurement. In order to assess the magnitude and distributions of these changes, we gridded the values of S, DIC, NO_3 , Si(OH)_4 and AOU of each dataset and subtracted the grids from each other. Grid spacing was every 2 degrees of latitude, with 80 layers in the vertical direction, with increased density towards the surface. The differences deeper than 400 dbar (i.e. the deepest extent of the winter mixed layer; Dong et al. 2008) are very modest, having average values (for S, DIC, NO_3 , Si(OH)_4 and AOU) of 0.004 ± 0.047 ; $1.5 \pm 12.2 \mu\text{mol kg}^{-1}$; $2.15 \pm 6.37 \mu\text{mol kg}^{-1}$; $-3.7 \pm 11.5 \mu\text{mol kg}^{-1}$; $1.2 \pm 15.0 \mu\text{mol kg}^{-1}$, respectively. Due to greater seasonality one would expect larger variability in the upper 400m, which we do see, however, the differences remain of a similar order of magnitude with average differences of 0.122 ± 0.404 ; $6 \pm 18 \mu\text{mol kg}^{-1}$; $3.51 \pm 8.02 \mu\text{mol kg}^{-1}$; $1.4 \pm 3 \mu\text{mol kg}^{-1}$; $0.9 \pm 19 \mu\text{mol kg}^{-1}$ for S, DIC, NO_3 , Si(OH)_4 and AOU, respectively.

2.4 eMLR and C_{ant} Calculations

There are two general carbon data-based approaches for studying the increasing oceanic C_{ant} . The first approach uses back-calculation techniques (e.g. ϕC_T , ΔC^* , TrOCA) to obtain an estimate of pre-industrial DIC concentration against which to compare current measurements. Methods from the second approach aim to determine the part of change in DIC between two specific time periods that is attributable to anthropogenic CO_2 invasion (e.g. multi-linear regression, time series residuals). One example of each approach is employed in this study [eMLR (Friis et al., 2005) and ϕC_T (Vázquez-Rodríguez et al., 2009a, 2009b)]. Various comparison and evaluations of these and other methods are available in the literature (Levine et al., 2008; Yool et al., 2010; van Heuven et al., 2011b; Sabine and Tanhua, 2010).

2.4.1 ΔC_{ant} from eMLR

The multi-linear regression approach to estimating anthropogenic CO_2 invasion was introduced by Wallace (1995). It involves using a number of biogeochemical properties,

known to be related to DIC, to obtain a model of the observed DIC. As the relationships between DIC and these properties are not expected to change over time, the same statistical relationships can be applied to a second dataset of later date. Differences between the model ‘predicted’ DIC and the observed DIC are attributed to the invasion of anthropogenic CO₂. In the extended version (eMLR), which is applied here, the DIC from both datasets is fitted to the same selection of properties from both datasets, and the difference between parameter coefficients is assumed to be predictive of the difference in C_{ant} between the two cruises:

$$\Delta C_{\text{ant}}^{\text{eMLR}} = \text{DIC}^{\text{MLR2,t2}} - \text{DIC}^{\text{MLR1,t1}} \quad (1)$$

$$= (a_2 - a_1) + (b_2 - b_1) S_{\text{t2}} + (c_2 - c_1) \text{SiO}_{2\text{t2}} + (d_2 - d_1) \text{NO}_{3\text{t2}} \\ + \dots (e_2 - e_1) T_{\text{t2}} + (f_2 - f_1) \text{AOU}_{\text{t2}}. \quad (2)$$

Using a stepwise regression the most significant terms for the WOCE A17 ‘94 dataset were determined as, in order of decreasing importance: S, SiO₂, NO₃, T, and AOU. These properties predict DIC with an R² value of 0.99 and a root mean square error (rmse) of 6.66 μmol kg⁻¹. For the GEOTRACES-NL (2010/2011) dataset, the order of importance was: S, SiO₂, NO₃, T and AOU, with an R² of 0.98 and rmse of 9.87 μmol kg⁻¹ (Fig. 2).

Figure 2. The residuals of the MLR fits of the (a) WOCE ‘94 A17 and (b) GEOTRACES-NL (2010/2011) datasets.

Table 1. Differences between the fitted coefficients for the two data sets obtained on the WOCE '94 A17 and the GEOTRACES-NL (2010/2011) cruises. The listed parameters were fitted to DIC for the applied eMLR method at various density intervals.

Min density	Max density	Mean Layer Depth	a	Si(OH) ₄	NO ₃	S	Theta	AOU	Pressure	rmse	R ²	n

The eMLR regressions were applied along isopycnals intervals, consistent with the idea that the preferred method of water movement from the surface into the ocean interior is along surfaces of constant density. It thus follows that waters occupying the same density band share a common formation history and can be described by a single equation. Isopycnal bands were chosen based on temperature-salinity plots of the water masses and the number of data points occupying each interval. The coefficients and accompanying statistics from each isopycnal interval are displayed in Table 1. The residuals of each fit are shown in Fig. 2, with the 2011 dataset showing a maximum average residual of 7 $\mu\text{mol kg}^{-1}$, in the surface layer and an overall average of 2.1 $\mu\text{mol kg}^{-1}$ including the deeper waters (>2000 dbar). In comparison, the WOCE '94 A17 dataset shows a water column average residual of 3.17 $\mu\text{mol kg}^{-1}$, which we attribute to less precise measurements in the earlier dataset. Pressure was included in the regression to avoid skewing (over depth) of the residuals of the MLR by the relatively large amount of samples located towards the surface, as mentioned by Hauk et al. (2010).

2.4.2 C_{ant} from φC_T°

The φC_T° method is a back-calculation approach that uses stoichiometric ratios from biogeochemical processes to account for the addition of DIC in the water column resulting from organic matter remineralization and calcium carbonate dissolution, since the time of water formation. It is based on the general principle of ‘preformed DIC’ (or C_T°) of Brewer (1978) and ΔC^* of Gruber et al. (1996). The main advantage of this method is that it considers the non- steady state of A_T and $p\text{CO}_2$ in the subsurface reference layer.

2.5 Buffer Factors

The Revelle factor was originally described by Revelle and Suess (1957) and quantified the attenuated response of increasing DIC impacted by increasing $p\text{CO}_2$, or vice versa. This work has been built upon by Frankignoulle (1994) and more recently by Egleston et al. (2010), who outlined six expressions that define how $[\text{CO}_2]$, $[\text{H}^+]$, and Ω_{Ar} or Ω_{Ca} , are impacted by changes in DIC or A_T . The following three equations, taken from Egleston et al. (2010), are the expressions for the three buffer factors relating to DIC which were applied to the GEOTRACES-NL (2010/2011) southwest Atlantic section:

$$\gamma_{\text{DIC}} = (\partial \ln[\text{CO}_2] / \partial \text{DIC})^{-1} = \text{DIC} - \text{Alk}_C^2 / S, \quad (3)$$

$$\beta_{\text{DIC}} = (\partial \ln[\text{H}^+] / \partial \text{DIC})^{-1} = \text{DIC} \times S - \text{Alk}_C^2 / \text{Alk}_C, \quad (4)$$

$$\omega_{\text{DIC}} = (\partial \ln \Omega / \partial \text{DIC})^{-1} = \text{DIC} - \{ \text{Alk}_C \times P / [\text{HCO}_3^-] \}, \quad (5)$$

$$\text{where DIC} = [\text{CO}_2] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}], \quad (6)$$

$$\text{Alk}_C = [\text{HCO}_3^-] + 2[\text{CO}_3^{2-}], \quad (7)$$

$$P = 2[\text{CO}_2] + [\text{HCO}_3^-], \quad (8)$$

$$S = [\text{HCO}_3^-] + 4[\text{CO}_3^{2-}] + [\text{H}^+] + [\text{OH}^-] + \dots \\ \{[\text{H}^+][\text{B}(\text{OH})_4^-]/K_{hb} + [\text{H}^+]\} \quad (9)$$

and Ω refers to the saturation state of sea water with respect to aragonite or calcite. These equations quantify the resistance to change of $[\text{CO}_2]$ (represented by γDIC), $[\text{H}^+](\beta\text{DIC})$ and $\Omega(\omega\text{DIC})$ in a water mass to changes in DIC. The concentrations used for the calculations were obtained from CO2SYS (Lewis and Wallace, 1998, adapted for Matlab by van Heuven, 2011a) using the same input conditions as previously mentioned (Sect. 2.2.3).

3 Hydrography of the South Atlantic Ocean

The distributions of potential temperature, salinity, AOU, silicate, A_T , and DIC of the GEOTRACES-NL (2010/2011) section are shown in Fig. 3(a-f). The large water masses have been described elsewhere (Mémery et al., 2000; Ríos et al., 2010; Wanninkhof et al., 2010), thus here the treatment is relatively brief. Located deeper than 4500 dbar throughout the section is Antarctic Bottom Water (AABW), characteristic in its high DIC and AOU. Values for DIC in this water mass range from 2243 to 2267 $\mu\text{mol kg}^{-1}$, and AOU values occupy a narrow band between 111 to 128 $\mu\text{mol kg}^{-1}$. The DIC maximum (2267 $\mu\text{mol kg}^{-1}$) and potential temperature minimum (-0.16°C) of the entire section are both found in this water mass, which also shows the greatest A_T value (2369 $\mu\text{mol kg}^{-1}$), occurring below the upper 1000m. These characteristics are all representative of the old age of the water mass and are caused by the large amount of organic matter remineralization which has taken place within it. The AABW can, most easily, be distinguished from the overlying *lower* Circumpolar Deep Water (*l*CDW), by the high silicate concentrations, which reach values greater than 120 $\mu\text{mol kg}^{-1}$ in AABW. Silicate concentrations in the deep waters (>4000 dbar) demonstrate a strong covariance with A_T ($R^2=0.95$), which has been previously noted (Broecker and Peng, 1982; Ríos et al., 1995; Pérez et al., 2002) and stems from the simultaneous dissolution of opaline and calcium carbonate shells from the hard tissue of organisms (Pérez et al., 2002).

The *l*CDW has a core at approximately 3500 dbar at 50°S , above which it merges into *upper* Circumpolar Deep Water (*u*CDW), with its respective core identified by an oxygen minimum at approximately 1500 m (Mémery et al., 2000). Both branches of CDW display properties similar to that of AABW, as they represent a mixture of AABW and Weddell Sea Deep Water (Wong et al., 1998; Orsi et al., 1999). The *u*CDW and *l*CDW share isopycnals with *upper* North Atlantic Deep Water (*u*NADW) and *lower* North Atlantic Deep Water

(*l*NADW), respectively, in the northern half of the section. The *u*CDW and *u*NADW occupy the density band between $\sigma_\theta > 27.4$ and $\sigma_3 < 41.47$, with the front between the two water masses found at approximately 26°N (Mémery et al., 2000). The NADW has been more recently ventilated than CDW and can thus be distinguished by lower AOU values of $\sim 60 \mu\text{mol kg}^{-1}$ and DIC values lower than $2200 \mu\text{mol kg}^{-1}$. The deeper *l*NADW can be separated from *u*NADW through higher silicate values, which rise to $40 \mu\text{mol kg}^{-1}$, whereas *u*NADW has maximum silicate concentrations of $20 \mu\text{mol kg}^{-1}$ (Fig. 3d). The A_T values are also lower ($\sim 20 \mu\text{mol kg}^{-1}$) in *u*NADW compared to *l*NADW.

The Antarctic Intermediate Water (AAIW) enters the section at 200 dbar just south of 48°S, identifiable as a tongue of water with very low salinity and A_T (minima of 34.05 and $2275 \mu\text{mol kg}^{-1}$, respectively). The AAIW lies above *u*CDW and below SubAntarctic Mode Water (SAMW) (Peterson and Whitworth, 1989). This water mass is carried northward at intermediate depths between $\sigma_\theta > 27.1$ and $\sigma_\theta < 27.4$ (Ríos et al., 2012) from south of the SAF. In the southwestern Atlantic Ocean AAIW extends further north than in other oceans, due to the western boundary current along the coast of South America (Talley, 1996). The AAIW is a relatively young water mass and has AOU values comparable to NADW ($\sim 50 - 100 \mu\text{mol kg}^{-1}$), however, it can be distinguished from *u*NADW, in its northward reaches, by its elevated silicate concentrations. Situated above the AAIW, the SAMW can be considered a component of the AAIW (McCartney, 1977). This water mass can be easily identified by the tracer $\text{Si}^* = [\text{Si}(\text{OH})_4] - [\text{NO}_3^-]$ which has values from -10 to $-15 \mu\text{mol kg}^{-1}$ in regions of SAMW formation (Sarmiento et al., 2004). The SAMW formation region is located just south of 47°S in the Subantarctic Zone (SAZ), north of the SAF (McCartney, 1977) where deep winter mixing forms this high-oxygen water mass.

We estimate the Subtropical Front (STF) at $\sim 41^\circ\text{S}$, where there is a steep gradient in salinity in the surface 200 dbar. North of the STF, in the surface, and extending northward to a density of $\sigma_\theta < 26.5 \text{ kg m}^{-3}$, is South Atlantic Central Water (SACW; Ríos et al., 2012), which is heavily depleted in silicate, and has elevated salinity and A_T . Against this background, the two Amazon plumes are very distinct at 5°N and 15°N with salinity and A_T values as low as 34.11 and $2265 \mu\text{mol kg}^{-1}$, and 32.3 and $2157 \mu\text{mol kg}^{-1}$, respectively. The maximum values of both salinity and A_T correspond with South Atlantic Central Water (SACW) in the subtropics (17°S), reaching absolute maxima of 37.5 and $2456 \mu\text{mol kg}^{-1}$, respectively, at 50 dbar depth. The subtropical part of the SACW that features high salinity and A_T is often referred to as the Salinity Maximum Water (SMW). In this study we make no distinction between SMW and SACW.

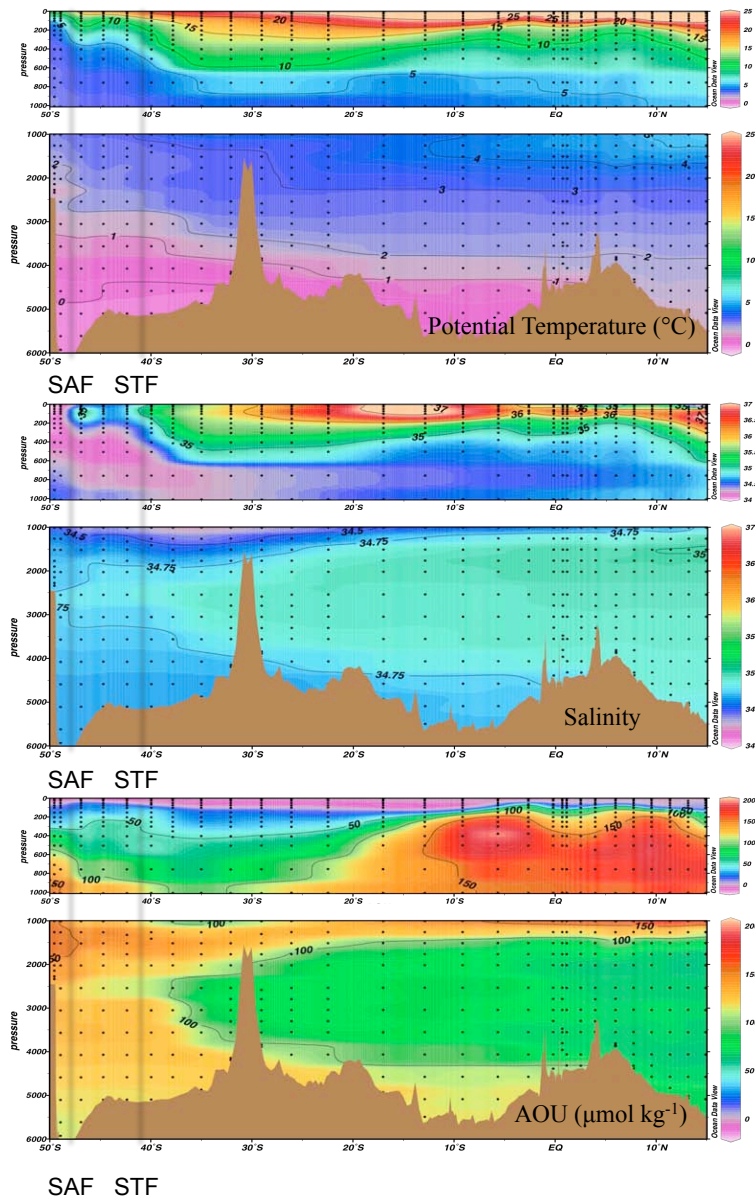

Figure 3. Section distributions of (a) temperature ($^{\circ}\text{C}$), (b) salinity, (c) AOU ($\mu\text{mol kg}^{-1}$), collected on the GEOTRACES-NL (2010/11) cruises. Black solid lines represent the SubAntarctic front (SAF) and Subtropical Front (STF) at the surface.

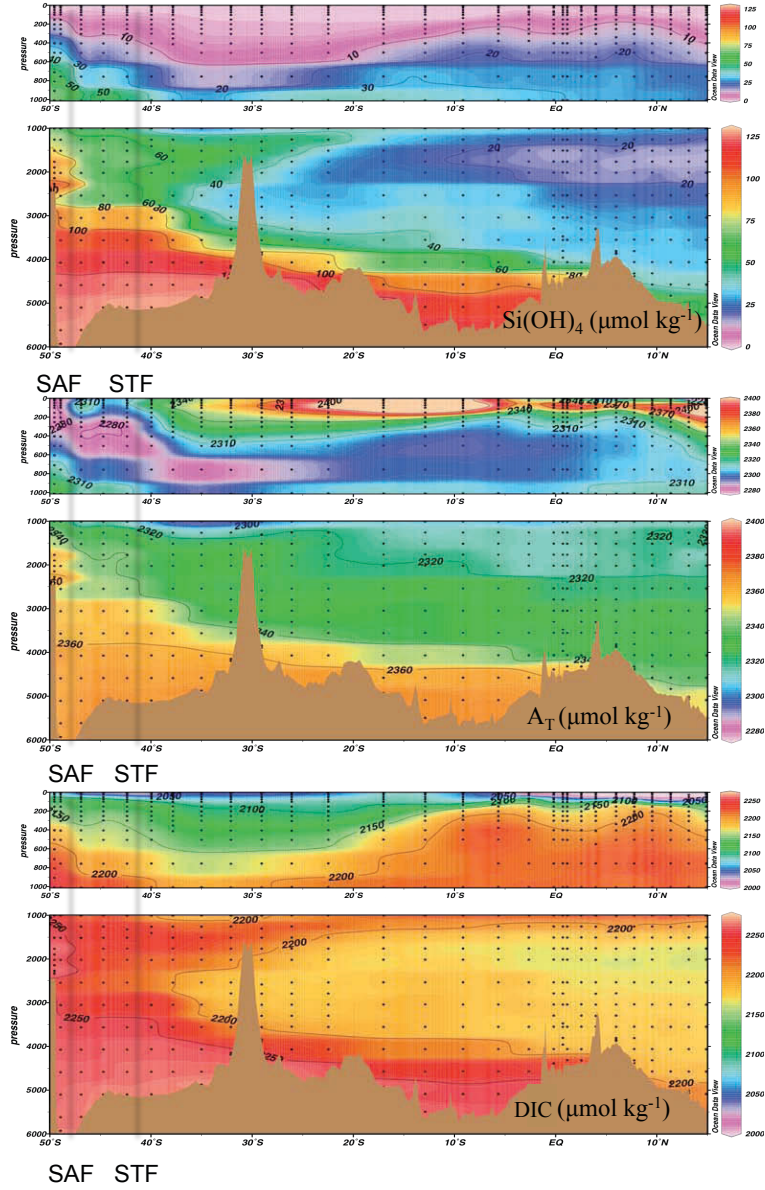

Figure 3. Section distributions of (d) silicate ($\mu\text{mol kg}^{-1}$), (e) A_T ($\mu\text{mol kg}^{-1}$) and (f) DIC ($\mu\text{mol kg}^{-1}$), collected on the GEOTRACES-NL (2010/11) cruises. Black solid lines represent the SubAntarctic front (SAF) and Subtropical Front (STF) at the surface.

4 Results

4.1 ΔC_{ant} from eMLR

The increase in C_{ant} (ΔC_{ant}) from 1994 to 2011, obtained from an eMLR analysis, is shown in Fig. 4a. The general pattern is that from 1994 to 2011 the most evident increase in C_{ant} occurred in the upper 1000 dbar, particularly in the southern half of the section. The largest increases (up to $36 \mu\text{mol kg}^{-1}$) were found in the surface waters of the SAZ, just south of 45°S . In the surface waters (<100 dbar) of the section the ΔC_{ant} gradually decreases northwards in a linear relationship with latitude ($R^2 = -0.74$) to a concentration of $0 \mu\text{mol kg}^{-1}$ just north of the equator ($\sim 5^\circ\text{N}$). This follows the pattern expected from surface water temperature, which plays a large role in determining the surface ocean $p\text{CO}_2$ and contributes to the role of the equatorial region acting as a source of CO_2 to the atmosphere during austral summer (Takahashi et al., 2009). The steepest vertical gradient of ΔC_{ant} is found at $\sim 47^\circ\text{S}$ just north of the SAF, where over the depth range from 600 to 0 dbar the ΔC_{ant} increases from 0 to $36 \mu\text{mol kg}^{-1}$.

South of 15°S the deepest penetration of positive ΔC_{ant} values is found at 1200 dbar in the STZ, between 25°S and 40°S . The ΔC_{ant} zero-contour shoals southward of 35°S to ~ 600 dbar at 50°S , coinciding with the lower limits of AAIW, as has been noted in other ocean basins (Sabine et al., 2004). In the northern half of the section, the deepest limit of ΔC_{ant} penetration in AAIW reaches a depth of ~ 700 dbar at 15°S and north of the equator the AAIW signal becomes distorted as it mixes with NADW. The NADW shows near-zero concentrations of ΔC_{ant} throughout its extent, with the exception of the $u\text{NADW}$ in the equatorial region, which show ΔC_{ant} values up to $5 \mu\text{mol kg}^{-1}$. In $l\text{NADW}$, and the other deep and bottom waters (AABW, $l\text{CDW}$), ΔC_{ant} shows no change or a tendency to negative values.

Water Mass	Density Range	Latitude	Pressure (dbar)	δC_{ant} ($\mu\text{mol yr}^{-1}$)	$^a\delta C_{\text{ant}}$ ($\mu\text{mol yr}^{-1}$)	$\delta\text{pH yr}^{-1}$
SACW	$\sigma^{\theta}20.0\text{--}\sigma^{\theta}26.8$	23 - 18°S	90-160	0.99 ± 0.14	0.90 ± 0.04	-0.0016
SAMW	$\sigma^{\theta}26.5\text{--}\sigma^{\theta}27.1$	48 - 50°S	90-160	0.53 ± 0.11	0.53 ± 0.02	-0.0014
AAIW	$\sigma^{\theta}27.1\text{--}\sigma^{\theta}27.4$	48 - 50°S	360-450	0.36 ± 0.06	0.36 ± 0.02	-0.0010
$u\text{CDW}$	$\sigma^{\theta}27.4\text{--}\sigma^341.47$	49 - 50°S	1400-1800	0.33 ± 0.07	0.16 ± 0.04	-0.0010
$u\text{NADW}$	$\sigma^{\theta}27.4\text{--}\sigma^341.47$	10 - 15°N	1600-1800	0.20 ± 0.03	0.16 ± 0.04	-0.0005
$l\text{CDW}$	$\sigma^341.47\text{--}\sigma^445.9$	48 - 50°S	3250-3750	0.00 ± 0.06	0.08 ± 0.04	0.0000
$l\text{NADW}$	$\sigma^341.47\text{--}\sigma^445.9$	10 - 15°N	3000-3500	0.00 ± 0.02	0.08 ± 0.04	0.0000

Table 2. The calculated rates of increase of C_{ant} and pH along the section, listed per water mass. The identification criteria for each water mass are provided. Error represents $2\sigma/\text{N}^{0.5}$. ^aValues from Ríos et al. (2012).

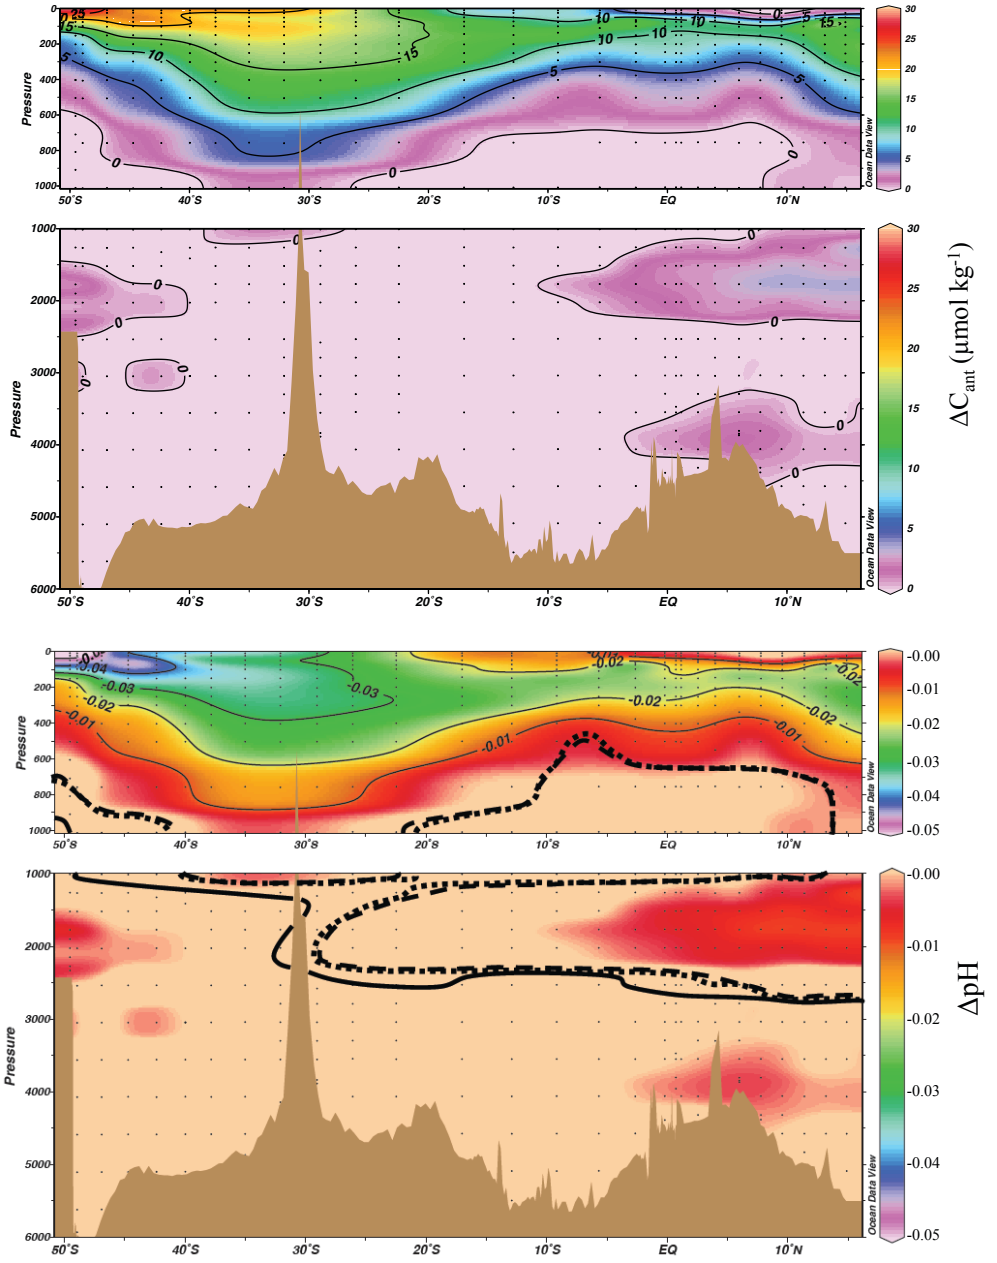

Figure 4. (a) Distribution of $\Delta C_{\text{ant}}^{1994-2011}$ ($\mu\text{mol kg}^{-1}$), calculated using the eMLR approach. (b) Distribution of the $\Delta\text{pH}^{1994-2011}$ associated with $\Delta C_{\text{ant}}^{1994-2011}$. The aragonite saturation horizon (ΩAr) is marked on for pre-industrial times (solid line), 1994 (dashed line) and 2011 (dotted line).

To estimate the rate of increase of C_{ant} in each water mass we identified their respective cores using the water mass descriptions given in Mémery et al. (2000) and Ríos et al. (2012) and averaged their values of ΔC_{ant} . Assuming a constant yearly increase, we then divided this total increase by 17 to obtain the rate of yearly increase of C_{ant} over the period 1994 to 2011. The calculated values are shown in Table 2 with those of Ríos et al. (2012) for comparison. The highest rates of increase were found in SACW and SAMW with C_{ant} increase rates of $0.99 \pm 0.14 \mu\text{mol kg}^{-1} \text{y}^{-1}$ and $0.53 \pm 0.11 \mu\text{mol kg}^{-1} \text{y}^{-1}$, respectively. The latter value shows good consistency with that calculated by Ríos et al. (2012; $0.53 \pm 0.02 \mu\text{mol kg}^{-1} \text{y}^{-1}$). However, there is a notable difference of $0.09 \mu\text{mol kg}^{-1} \text{y}^{-1}$ between the increase for SACW calculated here and that of $0.90 \pm 0.04 \mu\text{mol kg}^{-1} \text{y}^{-1}$ (Ríos et al., 2012). As this is a surface water mass, and our study utilized data collected 6 years after that used for comparison in Ríos et al. (2012), we corrected the ΔC_{ant} as follows. Assuming complete equilibration between the atmosphere and ocean we corrected our ΔC_{ant} value for the additional DIC increase caused solely by atmospheric increases over the last 6 years, assuming constant salinity and A_T . The resulting calculated $C_{\text{ant}}^{1994-2005}$ increase rate was $0.92 \pm 0.14 \mu\text{mol kg}^{-1} \text{y}^{-1}$, making our result consistent with the previous estimate. As such, we attribute the difference in ΔC_{ant} increase rates in SACW to changing atmospheric $p\text{CO}_2$ concentrations between sampling times. Despite the similarities in formation history between SAMW and AAIW, the latter shows a much lower increase rate of $0.37 \pm 0.06 \mu\text{mol kg}^{-1} \text{y}^{-1}$. Increase rates of $0.33 \pm 0.07 \mu\text{mol kg}^{-1} \text{y}^{-1}$ and $0.20 \pm 0.03 \mu\text{mol kg}^{-1} \text{y}^{-1}$ were calculated for $u\text{CDW}$ and $u\text{NADW}$, respectively. The $l\text{NADW}$, $l\text{CDW}$ and AABW all show no significant increases.

4.2 Changes to pH and buffering capacity

Assuming no changes of A_T between the WOCE '94 A17 and GEOTRACES-NL (2010/2011) occupations, we use the calculated ΔC_{ant} and the measured A_T during GEOTRACES-NL (2010/2011) to calculate the anthropogenic driven change in pH from 1994 to 2011 ($\Delta\text{pH}^{1994-2011}$). From the application of the φC_T^0 method of anthropogenic carbon determination (Vázquez-Rodríguez et al., 2009a, 2009b; Sect. 2.3.2) we obtain the C_{ant} signal since pre-industrial times, which allows the calculation of the decline in pH, which has occurred since pre-industrial times (ΔpH) (Fig. 4b). The average surface (<250 dbar) ΔpH , across the section, from pre-industrial times to 1994, calculated using the φC_T^0 method, was -0.08, which is just under the predicted, general surface ocean decrease of 0.1 (Orr et al., 2005). The ocean interior experienced relatively small ΔpH , however, the change was accompanied by a significant shoaling of the aragonite saturation horizon, most notably in the southern half of the section (Fig. 4b). South of the SAF, at $\sim 49^\circ\text{S}$, the aragonite saturation horizon rose by ~ 250 m, whereas further north, at 25°S , it had risen just 200 m. The change was almost imperceptible north of the Equator. From 1994 to 2011 the surface pH shows an averaged, further decline of 0.03, making the total surface ΔpH -0.11 since pre-

industrial times. Thus, of the total decrease since pre-industrial times to the present day, 27% occurred within the past 17 years. However, we can detect no notable change to the aragonite saturation state during this latter period. Historically, the uptake of C_{ant} by the surface ocean was relatively gradual, which allowed it to be well distributed throughout the water column. The effects of the recently, steeply decreasing anthropogenic acidification have not yet significantly penetrated into the deeper ocean.

The distribution of $\Delta\text{pH}^{1994-2011}$ across the section broadly follows the C_{ant} increases (compare Figs 4a, 4b), as expected under the assumption of a constant A_T . If we further assume a constant decrease over the 17 years, the yearly acidification rates were calculated from $\Delta\text{pH}^{1994-2011}$ and identified for each water mass core, as done for the yearly C_{ant} increases (Table 2). The highest rates of acidification were found in the surface waters, where we also observe the greatest rates of C_{ant} increase, with SACW showing a pH rate of decrease of -0.0016 yr^{-1} . The latter value is in line with that calculated for the same water mass on the eastern side of the North Atlantic Ocean at the ESTOC site (-0.0017 yr^{-1}) for the period 1995 to 2004 (Santana-Casiano et al., 2007; González-Dávila et al., 2010). The SAMW demonstrates the next greatest rate of decline with -0.0014 yr^{-1} , followed by AAIW and μCDW both showing acidification rates of -0.001 yr^{-1} , which are comparable with values from other recently ventilated water masses in the North Atlantic: acidification rates of -0.0019 yr^{-1} and -0.0012 yr^{-1} have been reported for SubArctic Intermediate Water and SubPolar Mode Water, respectively (Vázquez-Rodríguez et al., 2012). The lowest non-zero acidification rate of -0.0005 yr^{-1} is found in μNADW .

5 Discussion

The distribution of ΔC_{ant} and the increase rates of C_{ant} calculated here show good consistency with previous studies (Ríos et al., 2010; Wanninkhof et al., 2010; Ríos et al., 2012). In contrast to our calculated ΔC_{ant} , a number of studies have found increasing concentrations of C_{ant} in AABW (Murata et al., 2008; Vázquez-Rodríguez et al., 2009; Brown et al., 2010). However, it has been noted previously that it is absent in eMLR analyses (Wanninkhof et al., 2010). The distributions of C_{ant} in AABW presented in Vázquez-Rodríguez et al. (2009) also indicate that C_{ant} concentrations have not yet spread further north than 50°S , potentially explaining its absence in our calculations. Analysis of changes in the surface waters are usually overlooked due to the larger residuals associated with the presence of biological activity and seasonal variability (Friis et al., 2005), however, here we give these results validation.

The SAZ is typically under-saturated with respect to CO_2 (Metzl et al., 1999) due to a

combination of low temperatures and biological activity (McNeil et al., 2007). Calculation of $p\text{CO}_2$ using DIC and A_T shows that during both the WOCE '94 A17 and GEOTRACES-NL (2010/11) cruises the surface waters in the SAZ were under-saturated with respect to atmospheric $p\text{CO}_2$, at 311.5 μatm and 355.2 μatm , respectively (atmospheric $p\text{CO}_2$ was 359 μatm in 1994 and 392 μatm in 2011, ftp://ftp.cmdl.noaa.gov/ccg/co2/trends/co2_annmean_mlo.txt). The two years thus show relative consistency in $\Delta p\text{CO}_2$ ($p\text{CO}_{2\text{ocean}} - p\text{CO}_{2\text{atm}}$), with an average under-saturation of -47.5 μatm in 1994 and -38.8 μatm in 2011. Using average salinity, A_T , temperature and pressure in this region, this computes as a DIC difference of 4.4 $\mu\text{mol kg}^{-1}$ between the two years. Furthermore, principally the variability in both temperature and biology should be accounted for in the eMLR because of the use of temperature and biology-representative variables used (i.e. temperature, NO_3 and Si(OH)_4). However, the conceivably variable carbon export between the two time periods (due to variably dominant phytoplankton groups) may have lead to variation in the chemical stoichiometry, which could not be accounted for.

To corroborate our observations of surface ΔC_{ant} obtained using eMLR by another approach, we follow Lee et al. (1997) to derive a linear relationship between temperature and salinity normalized-DIC ($\text{NDIC} = \text{DIC} \cdot (35/S)$) for surface waters (<100 dbar) with a temperature greater than, or equal to, 19°C ($T \geq 19$) and lower than 19°C ($T < 19$). We derive such relationships for both WOCE '94 A17 and GEOTRACES-NL (2010/2011) data, with the resulting equations given below with those of Lee et al. (1997):

$$\text{Lee et al. (1997):} \quad T \geq 19^\circ\text{C}: \quad \text{NDIC} = 2136.3 - 6.97T \quad (10)$$

$$T < 19^\circ\text{C}: \quad \text{NDIC} = 2163.2 - 9.15T \quad (11)$$

$$\text{WOCE (1994):} \quad T \geq 19^\circ\text{C}: \quad \text{NDIC} = 2141 - 6.99T \quad (R^2=0.86) \quad (12)$$

$$T < 19^\circ\text{C}: \quad \text{NDIC} = 2209 - 10.69T \quad (R^2=0.96) \quad (13)$$

$$\text{GEOTRACES (2011):} \quad T \geq 19^\circ\text{C}: \quad \text{NDIC} = 2160 - 7.02T \quad (R^2=0.85) \quad (14)$$

$$T < 19^\circ\text{C}: \quad \text{NDIC} = 2246 - 11.09T \quad (R^2=0.99) \quad (15)$$

For $T \geq 19^\circ\text{C}$ the gradient, or slope, between temperature and NDIC is almost identical for all three datasets, varying from 6.90 to 7.02, which would result in a maximum NDIC difference of 2.6 $\mu\text{mol kg}^{-1}$ at 29.3°C (the maximum temperature recorded of both datasets). These temperatures cover the tropics to the mid-latitudes, reaching 40°S. The resulting equations, from the WOCE '94 A17 and GEOTRACES-NL (2010/2011) datasets, show an increasing intercept of NDIC of 19 (2160-2141) $\mu\text{mol kg}^{-1}$ from 1994 to 2011, which is consistent with the increase anticipated solely by increasing atmospheric $p\text{CO}_2$ (+20 $\mu\text{mol kg}^{-1}$). The

increase of intercept is also consistent with the ΔC_{ant} calculated using eMLR between latitudes 0° to 40°S (14 to 27 $\mu\text{mol kg}^{-1}$). North of the equator inconsistencies emerge between the estimated ΔC_{ant} values from the derived equation and from the eMLR analysis. In this region the $p\text{CO}_2$ of the ocean often exceeds that of the atmosphere (Takahashi et al., 2009), thus changes in temperature or other physical processes may exert controls undetectable by our analysis.

The colder temperature range ($<19^\circ\text{C}$), encompassing the higher latitudes ($>46^\circ\text{S}$), shows a slight steepening of the slope over the years in addition to an increased intercept. The observed increase in the intercept of 37 (2246-2209) $\mu\text{mol kg}^{-1}$ corresponds with the highest value of ΔDIC calculated using an eMLR (37 $\mu\text{mol kg}^{-1}$ at 49°S) at a temperature of 11.2°C . The variation in the slope ($11.09-10.69=0.4$) leads to a maximum difference of $\pm 7.6 \mu\text{mol kg}^{-1}$ DIC at 18.9°C between the calculated NDIC values from 1994 to 2011. This comparison increases our confidence in our ΔC_{ant} values calculated in the surface waters, however, we note that in the high latitude regions there is the potential for greater errors.

The continuing uptake of atmospheric CO_2 gradually depletes the naturally available carbonate ion in the surface ocean thereby decreasing the capacity to *buffer* further CO_2 uptake and leading to the gradual acidification of the seawater. The extent to which the pH is affected by the increase of DIC is dependent upon several properties, including temperature, pressure, and A_T , which together determine its *buffering* capacity. As DIC increases, assuming no other changes take place, the buffering capacity of the water is reduced as $[\text{CO}_3^{2-}]$ decreases and $[\text{CO}_2]$ increases. The A_T is not altered by the flux of atmospheric CO_2 into the ocean, however, it is affected by biological processes, notably the dissolution and formation of calcium carbonate, with dissolution dominating in deep waters and formation playing a more important role in the surface. Table 2 quantifies the extent to which the calculated ΔC_{ant} have impacted pH in the water masses of the southwest Atlantic Ocean. Examination of this table clearly shows that the rate of acidification per $\mu\text{mol kg}^{-1}$ of DIC is not equal between water masses. The SAMW, a relatively fresh, low alkalinity water mass, has an acidification rate of -0.0014 yr^{-1} , which is 88% of that of SACW, a warmer, more saline water mass. However, the C_{ant} increase rate of SAMW is only 54% that of SACW. The AAIW shows the same rate of acidification as $u\text{CDW}$, however, the increase of C_{ant} in $u\text{CDW}$ is 10% lower than that of AAIW. These differences can be attributed to the varying buffering capacities of the water masses.

The distributions of the sensitivities of $[\text{H}^+](\beta\text{DIC})$, $[\text{CO}_2](\gamma\text{DIC})$ and $\Omega_{\text{CaCO}_3} (\omega\text{DIC})$ to changes in DIC for the southwest Atlantic are shown in Fig. 5. The greatest sensitivities to increasing DIC (denoted by low values in figures 5a, 5b, and high values in 5c) were

generally found in the deep waters. That is to say that for a given increase in DIC these waters will show large resultant changes in $[H^+]$, $[CO_2]$ and $[CO_3^{2-}]$, or aragonite and calcite saturation (Ω_{Ar} , Ω_{Ca}). Both $uCDW$ and $lCDW$ show very similar behavior – as expected from their similar formation history – however, interestingly, there is a notable difference between the buffering capacities of the two limbs of NADW. The difference is most noticeable in ωDIC , likely caused by the slightly higher A_T/DIC ratio in $lNADW$. A lower βDIC in $uNADW$ denotes a greater sensitivity to acidification in response to increasing DIC concentrations. More rapid acidification in $uNADW$, compared to $lNADW$, has been observed by Vázquez-Rodríguez et al. (2012) and attributed to mixing with Labrador Sea Water (LSW), which exhibits a strong decreasing pH trend with time. The lower pH of LSW and its contribution to $uNADW$ could account for the reduced buffering capacity calculated in this water mass in the southwest Atlantic Ocean.

The highest βDIC values are found in SACW, and SAMW which both have relatively low concentrations of DIC compared to the other water masses but the highest concentrations of A_T . The three water masses with the greatest response in pH relative to ΔC_{ant} were AAIW, $uCDW$ and $lCDW$, with βDIC values of $0.148 \text{ mmol kg}^{-1}$, $0.141 \text{ mmol kg}^{-1}$, and $0.143 \text{ mmol kg}^{-1}$, respectively. These water masses show the highest DIC/A_T ratios along the section as they all originate in the Southern Ocean (SO) where upwelling brings deep waters rich in $[CO_2(aq)]$ and low in $[CO_3^{2-}]$ to the surface. In addition, these waters have slightly lower salinities and thus lower borate concentrations, which further diminish their buffering capacity. With the current calculated rate of increase of C_{ant} , aragonite will become under-saturated in AAIW around the year 2100, when DIC concentrations reach $2208 \text{ } \mu\text{mol kg}^{-1}$. This could happen even sooner, as wintertime, storm-driven upwelling entrainment of deep waters into the surface in the SO is predicted to cause seasonal aragonite under-saturation in the region as soon as 2030, when atmospheric CO_2 levels reach $\sim 450 \text{ ppm}$ (McNeil and Matear, 2008).

To quantify the differences between water masses in the context of increasing DIC, we calculate the respective changes in $[H^+]$, $[CO_3^{2-}]$ and pH in response to a $10 \text{ } \mu\text{mol kg}^{-1}$ increase in DIC in SACW and $uCDW$. In SACW such an increase would lead to a 3.87% increase in $[H^+]$ and a 2.51% decrease in $[CO_3^{2-}]$ with a pH decline of -0.0165. In contrast, the same increase in $uCDW$ leads to a +7.3% increase in $[H^+]$, -6.26% decrease in $[CO_3^{2-}]$ with pH decreasing by 0.0306 units. This makes $uCDW$ twice as susceptible to pH changes from increasing DIC than SACW and three times more susceptible to $[CO_3^{2-}]$ decreases and thus under-saturation of aragonite and calcite.

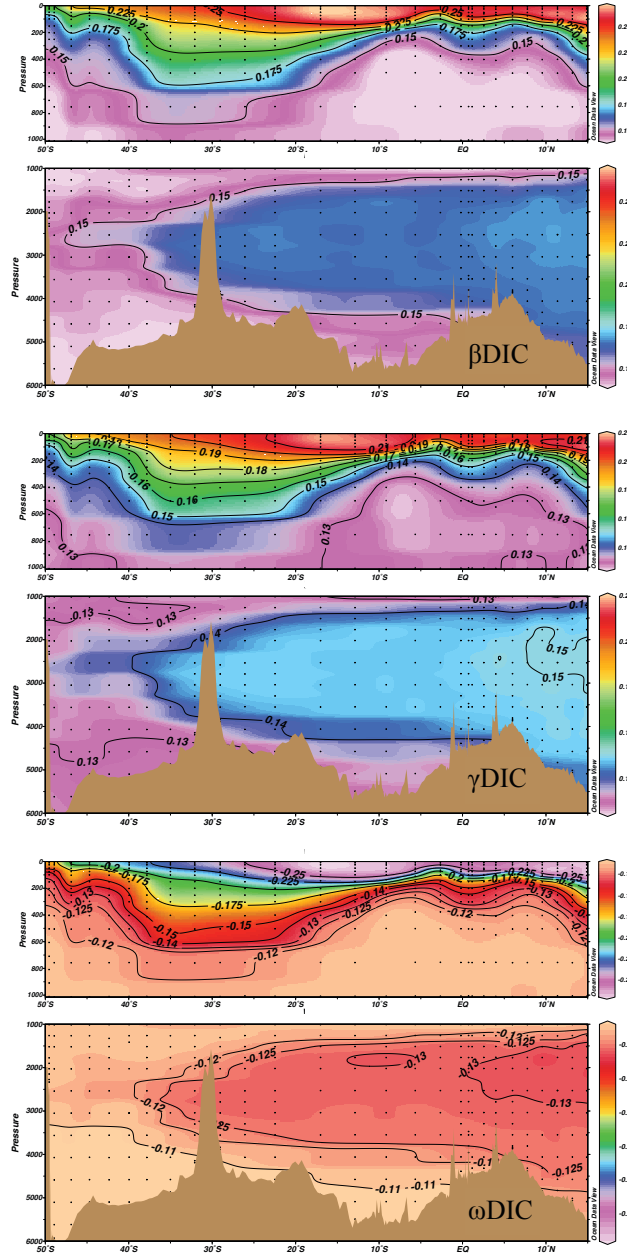

Figure 5. Distribution of the three buffering factors relating to DIC; β DIC, γ DIC, and ω DIC (mmol kg^{-1}).

The buffering capacity of each water mass will be further reduced by increasing the DIC concentrations. To investigate how the buffering capacities of the different water masses in this section have changed over time, and will continue to do so, the DIC buffer factors of each water mass were calculated and plotted against DIC concentration (Fig. 6). Due to the large relative error of the calculated ΔC_{ant} increases in the deeper waters, these were not included. The high rate of uptake of C_{ant} by SACW means that this water mass has seen the largest decrease in buffering capacity since pre-industrial times. The β_{DIC} value has decreased from 0.281 to 0.247 mmol kg⁻¹ and Ω_{Ar} has decreased from 4.1 to 3.3. In contrast, μCDW has shown relatively little change due to the low values of C_{ant} . However, extrapolating our calculated C_{ant} rates of increase we predict a 33 $\mu\text{mol kg}^{-1}$ increase in this water mass over the next century, which will result in a significant reduction in buffering and a pH decrease of -0.102. The SAMW and AAIW follow the same relationship, however, SAMW contains a greater proportion of subtropical water than AAIW, thus it maintains a slightly higher buffering capacity than AAIW. Both AAIW and μCDW will see a similar increase in C_{ant} over the next century (37 and 33 $\mu\text{mol kg}^{-1}$, respectively), however, the decline in Ω_{Ar} will be 1.6 times greater in AAIW, leading to under-saturation. The SAMW will see approximately 54% of the increase in C_{ant} that SACW will experience, however will undergo 84% of the associated pH decline. These changes highlight the vulnerability of SAMW and AAIW to increasing C_{ant} , as noted by Gonzalez-Davila et al. (2010).

The observed pattern of ΔC_{ant} in the southwest Atlantic clearly identifies the SAZ as the most effective entry point of C_{ant} into the ocean. In addition, the buffering factors of Egleston et al. (2010) explicitly show that by the end of this century the two dominant water masses in this area (SAMW and AAIW) will be the most sensitive to further C_{ant} increases. Whilst it is clear that this will accelerate the rate of acidification in these water masses, it is unclear how it will affect the CO₂ uptake in the SAZ. Assuming no changes to primary production, the increased sensitivity of SAMW to DIC changes will lead to much greater seasonal variability in the carbonate system of this water mass between the productive and non-productive period. The biological uptake of DIC in the SAZ in austral spring and summer would lead to a more dramatic decrease in surface water pCO₂, allowing a greater air-sea pCO₂ flux. Conversely, the acidification and decline in Ω_{Ar} may be detrimental to calcifying organisms in the area, as observed in the Southern Ocean (Bednarsek et al., 2012), thus limiting export via the biological pump. Additionally, SAMW plays a vital role in the ventilation and supply of nutrients to the thermocline (Karstensen and Quadfasel, 2002; Sarmiento et al., 2004) with models suggesting that this source of nutrients sustains almost three-quarters of primary production in the low latitudes (Sarmiento et al., 2004). As such, reductions to production and export in these regions may have significant consequences for other areas of the ocean as well.

Figure 6. The DIC buffer factors of each water mass over a range of DIC concentrations. The vertical lines denote the DIC concentration in pre-industrial times, 1994, 2011 and the projected concentration in 2110.

The water masses SAMW and AAIW both risk further reduction in their buffering capacities by long-term variability to their physical properties. On decadal time scales a freshening of AAIW has been observed in the Pacific and Indian sectors of the Southern Ocean (Wong et al., 1999). Decadal variability has also been noted in temperature, salinity and biogeochemical parameters of SAMW (Bindoff et al., 2007; Alvarez et al., 2011), which could further diminish or enhance the buffering capacity of this water mass and thus the C_{ant} driven acidification. Variations on decadal time scales have been related to the Southern Annular Mode (Álvarez et al., 2011), the dominant climate forcing over the region. Similarly in the North Atlantic, the North Atlantic Oscillation exerts a degree of control over the carbonate system variables and C_{ant} uptake (Santana-Casiano et al., 2007; Pérez et al., 2010). Such external controls will cause irregular C_{ant} uptake over time, as has been observed by Brown et al. (2010), making it difficult to accurately predict future C_{ant} uptake.

6 Conclusion

The continuing uptake of C_{ant} in the southwest Atlantic has been assessed through application of eMLR to two datasets collected in 1994 and 2011. The distribution of ΔC_{ant} is comparable with previous studies of C_{ant} accumulation in the region (Ríos et al., 2010). The largest increases are found in the SAZ, just north of the SAF; a previously identified substantial CO_2 sink (Metzl et al., 1999). The SACW ($0.99 \pm 0.14 \mu\text{mol kg}^{-1} \text{y}^{-1}$), SAMW ($0.53 \pm 0.11 \mu\text{mol kg}^{-1} \text{y}^{-1}$) and AAIW ($0.36 \pm 0.06 \mu\text{mol kg}^{-1} \text{y}^{-1}$) are responsible for the greatest C_{ant} uptake, consistent with earlier studies showing them to be an effective pathway of C_{ant} into the ocean interior (Álvarez et al., 2009). The lower extent of AAIW demarks the greatest depth of penetration of C_{ant} into the ocean in the past 17 years indicating that future uptake will similarly be largely concentrated within the surface 1000m.

The increase in C_{ant} in the southwest Atlantic has led to acidification of water masses. The calculated C_{ant} -driven acidification is greatest in SACW, where a current rate of pH decline of 0.0016 yr^{-1} is found. However, the acidification response per $\mu\text{mol kg}^{-1}$ increase in DIC is greatest in the intermediate and mode waters. We identify SAMW as the water mass with the greatest risk of rapid acidification, due to a combination of its high C_{ant} uptake and its limited buffering capacity. AAIW, on the other hand, is more at risk of aragonite under-saturation due its low A_T values and resultant high ωDIC values. Continued increase of C_{ant} at the current rate calculated will lead to aragonite under-saturation in the core of AAIW by 2104.

Chapter 7

Summary and Recommendations

7.1 Summary

Objectives

The object of this research was to investigate the buffering capacity of coastal and ocean systems of the Atlantic Ocean in light of the uptake of anthropogenic atmospheric carbon dioxide in these regions. A combination of data collected from nine cruises, a moored pCO₂ instrument and a three-year, on-going time-series have facilitated the analysis presented here. The different approaches to monitoring the oceanic carbonate system reflect the amount of variability in the different systems, which also present different challenges to discern the anthropogenic CO₂ trends from natural trends. The synthesis of all these approaches provides a comprehensive study of carbon dynamics in the Atlantic Ocean.

Internal Consistency

The fundamental thermodynamic principles governing the carbonate system in the ocean were published by Park in 1969. The equations outlined in this body of work were written primarily for use in deep waters, which are not in contact with the atmosphere or in the presence of substantial biological activity. The subsequent application of these equations to other marine environments is thus likely to introduce errors into the calculations as some of the governing assumptions no longer apply. It is thus not surprising perhaps, that when calculating a carbonate system parameter from two others, there is always an associated error (Wanninkhof et al., 1999; McElligott et al., 1998). In Chapter 2 we find that the error between calculated and measured parameters in the coastal ocean is approximately two times greater than that of the open ocean (Lee et al., 1997).

The diverse environments provided by the North Sea were successfully used to examine how the internal consistency varies between them. The most significant result was potentially the increasing difference between the performance of different carbonic acid dissociation constants in low salinity waters compared to high salinity waters. In the open ocean the differences are not noticeable, however, in coastal regions where the salinity falls below typical ocean values, the recommended constants of Mehrbach et al. (1973), refit by Dickson and Millero (1987) are no longer the most representative. Due to the increasingly large amount of work being carried out in coastal regions, this has large implications for future calculations of the carbonate system in these areas.

In higher salinity waters, which constitute the majority of the North Sea, the differences in internal consistency observed between different K₁ and K₂ parameterizations became insignificant compared to that caused by the input combinations for the calculations. All seasons displayed a similar level of internal consistency, with the exception of spring, which

was significantly worse. This is consistent with the findings of Koeve et al. (2011) and Hoppe et al. (2012) who both observe poor internal consistency in algal cultures and waters of high biological activity, which has been attributed to the contribution of organic matter to alkalinity. Here we show the same effect in a natural environment, however, again using the different biogeochemical regimes provided by the North Sea – the northern North Sea and southern North Sea – we find greater internal consistency in the south, which is associated with higher organic matter, indicating that this is not the primary cause of non-consistency in calculations. Instead, we can link this north-south pattern in internal consistency to the ratio of $A_T:DIC$, as noted by Lee et al. (1996). This study could not conclusively prove the source of errors in the calculations, and we find that this is an area, which would benefit from further work to better understand the carbonate system in coastal regions.

Terrestrial Significance

The influence of near-shore systems on coastal waters cannot be underestimated in studies of the carbon cycle. An example of this in the North Sea is the considerable influence of the Wadden Sea, which supplies large amounts of DIC and A_T to the southern North Sea throughout the year (Brasse et al., 1999; Thomas et al., 2009). In 2008 a time-series of A_T and DIC measurements was started in the Marsdiep basin – the largest basin of the Wadden Sea, facilitating an investigation into the controls of these parameters throughout the year (Chapter 3). Both DIC and A_T demonstrate a clear seasonal signal, with decreasing values throughout spring to late summer, and increasing values from summer to mid-winter. Whilst this pattern for DIC is easily explained by the annual cycle of photosynthesis, the A_T cycle shows the direct inverse to that of the adjacent southern North Sea and other coastal systems (Hydes et al., 2012). We deduce that the A_T fluctuations appear to be predominantly an effect of redox reactions within the nitrogen cycle highlighting the close interaction between nitrogen and carbon in the coastal environment. Furthermore, the magnitude of A_T generation between years appears to be linked to the initial diatom bloom, whose size is likely determined by the wintertime silicate concentration. The close interaction of sediment, water column and atmosphere in the Marsdiep leads to a high level of codependence between the carbonate system and phytoplankton succession and associated remineralization processes. The time series data presented is complemented by the collection of a broad range of chemical parameters facilitating such analysis. Despite this, a large number of assumptions must be made to localize the processes taking place in the carbon and nitrogen cycles. Further understanding of this system requires additional research into sedimentological processes and their impact on the water column, as in the Wadden Sea benthic remineralization can constitute up to 50% of remineralization (van Beusekom et al., 1999).

The Ocean Signal

The other significant influence on coastal regions, such as the North Sea, is the dominating ocean signal. Observations obtained in the late summer of 2001 and 2005 indicated a large decrease in the air-sea partial pressure difference of CO₂ ($\Delta p\text{CO}_2$), which is consistent with a decrease in the buffering capacity of the ocean. The same phenomenon was also observed in the adjacent North Atlantic Ocean (Lefèvre et al., 2004; Schuster and Watson, 2007; Thomas et al., 2008), indicating that it was not a local effect. An additional dataset collected in the late summer of 2008 complicated the matter by demonstrating no further change in buffering capacity or disproportionate $\Delta p\text{CO}_2$ thus leaving the reduction in buffering capacity between 2001 and 2005 unexplained. The change observed in the North Atlantic Ocean was attributed to the effects of the North Atlantic Oscillation Index, a measure of atmospheric pressure difference between the Azores and Iceland. The NAO was shown to exert significant control on the carbonate system in the North Atlantic Ocean, which thus supplies the majority of water and carbon to the North Sea, making it vital to understand these effects on a large scale so that we can anticipate the effects on a coastal scale.

The third occupation of the North Sea in 2008 facilitated the analysis of the effects of different NAO states on the carbonate system in the North Sea, as 2001, 2005 and 2008 coincided with years of negative, neutral and positive NAO indices, respectively (Chapter 4). The effects of NAO on the carbonate system in the North Sea are not all direct, as NAO influences precipitation patterns and water column stratification, which affect riverine runoff and phytoplankton blooms. The NAO also causes changes in the hydrographic properties of seawater, such as salinity and temperature, which directly impact the carbonate system. Within the North Sea, between the three years, we observed an increase in the DIC North Atlantic end member from 2001 to 2005 coinciding with a decrease in the DIC Baltic Sea end member. The latter being driven by greater precipitation over Scandinavia, the former being driven by changes in salt and heat exchange in the subtropical gyre of the North Atlantic Ocean. These changes led to an overall increase in the carbon inventory of the North Sea. From 2005 to 2008, which signified a change from neutral to positive NAO, there was no significant changes to the end members, however, the warmer summer combined with stronger North Atlantic inflow led to differences in mixing and mixed-layer depth and caused a strong gradient of pH between the southern North Sea and the northern North Sea. The sheer number of ways in which the NAO affects the North Sea make each change difficult to constrain and taking into account the varying time scales on which they operate complicates things further. However, we conclusively show that these effects are large enough to completely mask the expected increase in CO₂ driven by anthropogenic atmospheric increases.

Short-scale Perturbations

On the other side of the North Atlantic Ocean, the Scotian Shelf is a coastal system with more direct ocean influence. Chapter 5 sees the use of high-frequency CO₂ data to explain the diel carbon cycle throughout the year on the Scotian Shelf. Despite falling within the temperate latitude band, the Scotian Shelf constitutes an annual source of CO₂ to the atmosphere (Shadwick et al., 2011). During periods of warming (from April to August) a clear diel signal becomes apparent. Temperature-normalization was used to separate the temperature and biological controls on pCO₂ allowing us to identify the onset of net photosynthetic drawdown of CO₂, which lags the onset of photosynthetically available radiation (PAR) by up to 5 hours. The pCO₂ change attributed to biology was then further used to compute net community production (NCP). The maximum NCP calculated was 3.4 mol C m⁻², however NCP demonstrated a reduction up to 90% during summer time associated with the minimum in mixed layer depth. These results emphasize the significance of taking diel variability into account when working with pCO₂ data, as extrapolation of a value from different times of day can lead to substantial error margins.

Long-term Perturbations

On long time scales (>10 years) the ocean's role in anthropogenic carbon sequestration becomes much more significant than that of the coastal ocean. The Atlantic Ocean contains the highest proportion of global oceanic anthropogenic CO₂ per surface area (Sabine et al., 2004) and recent basin-wide inventories indicate that, currently, more effective uptake of Cant occurs in the southern half of the basin (Wanninkhof et al., 2010). The reoccupation of the historical WOCE A17 (1994) cruise track in 2010/11 facilitated a study of increasing Cant in the southwest Atlantic Ocean over more than a decade (Chapter 6). Using a combined approach of eMLR and ϕC_T^0 methods, we quantified the increase in Cant, which took place between 1994 and 2010/11 and calculated the associated change in pH. The largest C_{ant} increase of 37 $\mu\text{mol kg}^{-1}$ occurred in the SubAntarctic Zone, which is a well-documented CO₂ sink, whereas the deep waters (Antarctic Bottom Water, lower North Atlantic Deep Water, and lower Circumpolar Deep Water) showed no significant increases. Comparison of the calculated changes in Cant to changes in pH reveal the lowest buffering capacities, of the present water masses, lie in the mode and intermediate water masses. Thus, the increases in DIC have greater impact on pH in these two water masses. The significant Cant accumulation in these regions, accompanied by their high sensitivity to CO₂ increases, has caused a rapid drop in pH. If the current, calculated rate of increase of C_{ant} continues, we predict that these waters will be under-saturated with respect to aragonite by the year 2104.

Conclusions

This thesis has shown the importance of a multi-faceted approach to studying the ocean carbonate system. In temperate, coastal regions high frequency measurements are required in addition to measurements taken over longer time scales. The large amount of primary production which is supported in these regions mean that significant changes can occur over a few years, thus to put these changes in the context of change driven by anthropogenic forcing, a multitude of scales is necessary.

7.2 Recommendations

This thesis was designed to build upon previous work undertaken in the North Sea, using the datasets to quantitatively and qualitatively describe the changes in the North Sea carbonate system caused by anthropogenic CO₂ invasion. Due to the highly variable nature of coastal regions, this work was complemented by a time-series of carbon measurements adjacent to the North Sea, which began at the start of this PhD, and additional datasets from the Atlantic Ocean.

Limitations in oceanic carbon studies due to lack of internal consistency in the thermodynamic calculations remains a problem in this field. In this work we present the findings from the first internal consistency study conducted in a coastal environment on a seasonal scale (see Chapter 2). Our results support previous findings of a significant decrease in consistency between measured and calculated parameters in waters of high biological activity, which occur seasonally in temperate environments. Furthermore, even in abiotic waters, the internal consistency of coastal waters never reaches the same reproducibility found in open ocean waters. The presence of unaccounted for contributors to alkalinity is a very likely source of errors here. The field would greatly benefit from dedicated research in this area, as such a large number of studies rely on measuring two carbonate parameters and calculating one or two of the carbonate parameters. This is also an issue in lab environments, where algal cultures are grown in different CO₂ concentrations. In these experiments the quantity of water available for analysis is often limited, leading to analysis of two carbonate parameters and calculation of the remaining two.

One of the greatest challenges in temperate, coastal regions is to accurately constrain the CO₂ fluxes between the atmosphere and surface waters. The diversity of coastal regions means that each area is distinctly unique in behavior, thus making it impossible to extrapolate the results from one region to another. Whilst cruises offer excellent data coverage over an area, they are temporally limited as they offer just a ‘snapshot’ of the system at a particular time. The seasonal variability in temperate, coastal environments severely limits the use of such data to examine long-term CO₂-driven trends, or even annual deductions as to whether an area is an overall source or sink of CO₂ to the atmosphere. In the North Sea this problem has been largely helped by expeditions carried out in all four seasons. It is further resolved by the time-series measurements carried out at the NIOZ jetty. Until these time-series reach the maturity at which they can capture the natural variation exerted by climate forcing, there is a strong reliance on models to fill in the temporal gaps.

Modeling is one branch of investigation, which is not explored in this thesis, however, should not be overlooked. The ability of models to accurately represent the natural world provides a valuable tool against which to validate theories and to predict possible future scenarios. To facilitate the most correct portrayal it is vital to have a sound understanding of the underlying processes and how, and under what conditions they occur. As such, one should not neglect the importance of simple process studies, to determine the rates and pathways of carbon through the various pools (e.g. dissolved inorganic carbon, particulate inorganic carbon...) in coastal regions. Whilst this is not dealt with in this thesis, it is an area, which currently lacks quantitative information. The cycling of carbon in different environments is as varied as air-sea CO₂ fluxes, and thus efforts should also be made to understand the rates, and timescales, at which these processes operate.

An invaluable tool, which I would recommend here, would be the deployment of a continuous, underway monitoring device, such as a pCO₂ sensor, or pH measurement device. There has been a community-wide effort to develop such autonomous instruments over the past twenty years with great success. The data collected from such a device in the Scotian Shelf (see Chapter 5) has shown how valuable this data can be in capturing high-frequency data and determining the drivers of annual CO₂ fluxes in a region. Such data helps us to understand the dominant controls of air-sea CO₂ fluxes and thus better able to predict them in the future. The frequency of such measurements also allows us to examine processes occurring over a wide-range of time scales. A valuable, additional extension of such work is to relate the high-frequency CO₂ signal, with additional measured parameters, such as temperature, PAR, to satellite ocean colour measurements to extrapolate relationships between these parameters. The use of ocean color and satellite derived measurements to help quantify CO₂ fluxes and biological production holds great potential for future research, as it offers global coverage for relatively small monetary and time investments.

Since the production of certified reference material for dissolved inorganic carbon and total alkalinity there has been a substantial increase in the inter-comparability of carbon measurements between cruises and laboratories. Such improvements have facilitated the application of methods of anthropogenic carbon determination (e.g. TrOCA, ϕC_T^0) as well as the accurate quantification of changes in inorganic carbon between two measurement times (e.g. eMLR, ΔC^*). Such analyses are becoming increasingly popular and provide valuable insight to the destination of atmospheric anthropogenic CO₂, however, Brown et al. (2010) have shown that climatic forcing in the North Atlantic Ocean exerts a significant control on the annual CO₂ sink. It is likely that a similar process affects the uptake in other ocean basins, again stressing the importance of multiple occupations coupled with long time-series measurements.

On a global scale the Atlantic Ocean is the most studied Ocean with regards to the carbonate system. This could partly be because it contains the highest proportion of anthropogenic carbon of all the oceans, however, it is more likely due to the fact that it is bordered by the worlds' wealthiest countries, which have a vested interest in it. It thus follows that the seas and coasts of the worlds' poorest countries remain somewhat of a 'black box' with regards to carbon observations. Some of these systems are located in significant upwelling systems, and may provide further insight into the cycling, distribution and fate of carbon in the coastal region. Whilst a number of programs are in place to aid the development of science and facilitate research in these regions, I recommend further efforts to fill in these spatial holes in ocean carbon research and hopefully, simultaneously, holes in knowledge.

Nederlandse samenvatting

Koolstof is de meest fundamentele bouwsteen van het leven op deze planeet en het vierde meest overvloedige element in het universum. Met het begin van de Industriële Revolutie aan het einde van de 18e eeuw, de mens heeft versneld kooldioxide (CO₂) uitgestoten aan de atmosfeer door verbranding van fossiele organische koolstof welke voorheen voor lange termijn lagen opgeslagen. In de 20e eeuw is de atmosferische CO₂-concentratie met meer dan 20% gestegen, en het stijgingspercentage neemt nog steeds toe. Een groot deel van deze CO₂ wordt opgenomen door de oceanen, veranderen de chemie van zeewater in het proces, die kan potentieel hebben ontzettende gevolgen voor organismen leven in de oceaan en voor de toekomstige beperking van verdere atmosferische CO₂-stijgingen.

Eén van de belangrijkste vragen is hoeveel CO₂ wordt opgenomen door de oceanen en in welke gebieden dit het meest effectief gebeurt? Van continentale zeeën is al langer bekend dat hun bijdrage aan de primaire productie met betrekking tot hun oppervlakte onevenredig groot is, waardoor onderzoek in deze gebieden van groot belang is. Voor dit proefschrift is het carbonaat-systeem in de continentale zeeën, de kustwateren, en de open Atlantische Oceaan onderzocht om het lot en gevolgen van antropogene emissies van CO₂ in elk van deze omgevingen te bepalen.

Voordat we kunnen bepalen hoeveel en welk soort koolstof er in de oceanen is, moeten we begrijpen hoe goed onze metingen de werkelijkheid vertegenwoordigen. De thermodynamische grondbeginselen voor het carbonaat-systeem in de oceaan werden gepubliceerd door Park in 1969. De vergelijkingen die hierin werden voornamelijk geschreven voor gebruik in diepe wateren, die niet in contact zijn geweest met de atmosfeer en waarin weinig biologische activiteit plaatsvindt. Verdere toepassing van deze vergelijkingen in andere mariene milieus zal dus waarschijnlijk fouten introduceren in de berekeningen gezien sommige van de regerende veronderstellingen niet langer van toepassing zijn. Hier vinden we dat de fout tussen berekende en gemeten parameters in de kust gebieden ongeveer twee keer groter is dan die van de open oceaan.

De uiteenlopende milieus van de Noordzee werden vervolgens gebruikt om aan te tonen dat er een toenemend verschil is tussen de werking van verschillende koolzuurdissociatieconstanten in lager zoutgehalte wateren in vergelijking met hoge zoutgehalte wateren. In de open oceaan, zijn die verschillen zijn niet merkbaar, echter in kustregio's waar het zoutgehalte lager is dan typische oceaanwaarden, zijn de aanbevolen constanten van Mehrbach et al. (1973), refit Dickson en Millero (1987), niet langer de meest representatieve. Vanwege de steeds grotere hoeveelheid onderzoek dat wordt verricht in de kustregio's, heeft dit grote gevolgen voor de toekomstige berekening van het carbonaat-systeem in deze gebieden.

Terrestrische betekenis

De invloed van estuarine en getijden systemen mag in studies naar de koolstofcyclus in kustwateren niet worden onderschat. In 2008 startte een serie van A_T en DIC metingen in het Marsdiepbekken – de grootste bekken van de Waddenzee, om onderzoek naar de regulatie van deze parameters gehele jaar (hoofdstuk 3) te vergemakkelijken. Zowel DIC als A_T tonen een duidelijk seizoensgebonden signaal, met dalende waarden gedurende de lente tot de late zomer, en de oplopende waarden van zomer naar midwinter. Terwijl dit patroon voor DIC gemakkelijk te verklaren is door de jaarlijkse cyclus van fotosynthese verklaren is, toont de A_T -cyclus de directe inverse aan van de aangrenzende zuidelijke Noordzee. De schommelingen in de A_T -cyclus wordt veroorzaakt door een overheersend effect van redoxreacties binnen de stikstofcyclus en laten daarmee de nauwe interactie tussen stikstof en koolstof in de kust omgeving zien. Deze tijdreeksen zijn aangevuld met een breed scala aan chemische parameters ter vergemakkelijking van een dergelijke analyse. Ondanks dit, moet een groot aantal veronderstellingen worden gemaakt om processen die plaatsvinden in de koolstof en stikstofcycli te lokaliseren. Verder begrip van dit systeem vereist extra onderzoek naar sedimentologische processen en hun impact op de waterkolom.

Het signaal van de oceaan

De andere significante invloed op kustregio's, zoals de Noordzee, is het overheersende oceaansignaal. Drie bezettingen van de Noordzee tijdens perioden met een positieve, negatieve en neutrale Noord Atlantische Oscillatie index (NAO) vergemakkelijkt de analyse van de effecten van verschillende NAO regimes op het carbonaat-systeem in de Noordzee (hoofdstuk 4). De invloeden van de NAO op het carbonaat-systeem in de Noordzee zijn niet altijd direct, zoals bijvoorbeeld de NAO invloeden op neerslagpatronen en stratificatie van de waterkolom, die weer gevolgen hebben voor afvoer door rivieren en fytoplanktonbloeien. Daarnaast zorgt de NAO ook voor wijzigingen in de hydrografische eigenschappen van zeewater, zoals zoutgehalte en temperatuur, die rechtstreeks van invloed zijn het carbonaat-systeem. Tussen de drie verschillende jaren zien we dat in de Noordzee dat een DIC toename in het Noord Atlantische-aandeel van 2001 tot 2005 samenvalt met een daling in DIC in het Oostzee-aandeel. Het Oostzee-aandeel wordt veroorzaakt door meer neerslag over Scandinavië, terwijl het Noord Atlantische-aandeel wordt veroorzaakt door veranderingen in zout- en warmte-uitwisseling in de subtropische gyre van de Noord-Atlantische oceaan.

Deze veranderingen leidden tot een algemene toename van de koolstofvoorraad koolstof in de Noordzee. Van 2005 tot 2008, dat een overgang van neutrale naar positieve NAO betekende, was er geen significante veranderingen in de DIC concentratie van de verschillende water aandelen. Echter, de warmere zomer in 2008, gecombineerd met sterkere Noord-Atlantische instroom leidde tot verschillen in mengen en de diepte van de in de diepte

van de gemengde laag en veroorzaakte een sterke verloop van pH tussen de zuidelijke en de noordelijke Noordzee. Het aantal manieren waarop de NAO invloed heeft op de Noordzee maakt het moeilijk elke wijziging te beperken en rekeninghoudend met de verschillende tijdschalen waarop ze opereren bemoeilijkt de analyse nog meer. Echter blijkt onomstotelijk dat deze effecten groot genoeg zijn om de verwachte toename in CO_2 , gedreven door antropogene atmosferische verhogingen, volledig te maskeren.

Korte termijn verstoringen

Aan de andere kant van de Noord-Atlantische oceaan ligt de Scotian plat, een kuststelsel met meer directe invloed van de oceaan. Hoofdstuk 5 laat het gebruik van hoge-frequentie CO_2 -gegevens zien om de dagelijkse koolstofcyclus gedurende het hele jaar op de Scotian plat om uit te leggen. Ondanks dat the Scotian plat op een gematigde latitude ligt, vormt de Scotian plat een jaarlijkse bron van CO_2 naar de atmosfeer (Shadwick et al., 2011). Tijdens perioden van opwarming van de aarde (van April tot augustus) wordt er een duidelijk diel signaal zichtbaar. Temperatuur-normalisatie werd gebruikt om de temperatuur en biologische effect op pCO_2 te onderscheiden, waardoor het mogelijk is het begin van de netto fotosynthetische vermindering van CO_2 te bepalen, ondanks dat deze tot 5 uren achterloopt op het begin van fotosynthetische beschikbaar straling (PAR). De pCO_2 verandering toegeschreven aan biologie werd vervolgens verder gebruikt voor het berekenen van netto community productie (NCP). De maximale NCP berekend was 3.4 mol C m^{-2} , maar NCP liet een vermindering tot 90% tijdens de zomer, welke wordt geassocieerd met een minimum in de diepte van de gemengde laag. Deze resultaten benadrukken het belang om de diel variabiliteit mee te nemen bij het werken met pCO_2 gegevens, omdat extrapolatie van een waarde uit verschillende tijden van de dag tot substantiële fout marges leiden kan.

Lange termijn verstoringen

Op lange termijn (> 10 jaar) wordt de rol van de oceaan in het vastleggen van antropogeen koolstof veel belangrijker dan de rol van de kustgebieden. De Atlantische oceaan bevat het hoogste percentage van globale oceanische antropogene CO_2 emissies (Sabine et al., 2004) en recente inventarisaties van voorraden geven aan dat op dit moment meer C_{ant} effectief wordt opgenomen in de zuidelijke helft van het bekken (Wanninkhof et al., 2010). De herbezetting van de historische WOCE A17 (1994) cruise track in 2010/11 maakt een studie naar toenemende C_{ant} in de zuidwestelijke Atlantische oceaan over een tijdsperiode langer dan een decennium mogelijk (hoofdstuk 6). Met behulp van een gecombineerde aanpak van eMLR en ϕC_T^0 methoden, is de toename van C_{ant} , die plaatsvond tussen 1994 en 2010/11 en de bijbehorende wijziging in pH gekwantificeerd. De grootste C_{ant} toename van $37 \mu\text{mol kg}^{-1}$ is opgetreden in de SubAntarctic Zone, die een goed gedocumenteerde CO_2 -opslag is. Anderzijds blijkt dat de diepe wateren (Antarctische Bottom lower North Atlantic

Deep Water en lower Circumpolar Deep Water) geen significante toenames heeft plaatsgevonden.

Een vergelijking van de berekende veranderingen in C_{ant} ten opzichte van veranderingen in de pH laten zien dat de laagste buffercapaciteit van de huidige water massa, liggen in de mode en intermediate watermassa's. De stijging van DIC het dus een grotere impact op de pH in deze twee watermassa's. De aanzienlijke C_{ant} accumulatie in deze regio's, vergezeld met hun hoge gevoeligheid om CO_2 te laten toenemen, heeft geleid tot een snelle daling in pH. Als de huidige, berekende stijgingspercentage van C_{ant} constant blijft, voorspellen we dat deze wateren onderverzadigd met betrekking tot aragoniet zullen worden in 2104.

Conclusies

Dit proefschrift heeft het belang aangetoond van een veelzijdige aanpak bij het bestuderen van de oceaan carbonaatsysteem. In gematigde, kustgebieden zijn hoogfrequente metingen vereist naast metingen die op langere tijdschalen worden verricht. De grote hoeveelheid primaire productie die wordt ondersteund in deze regio's betekenen dat aanzienlijke wijzigingen kunnen plaatsvinden in een paar jaar. Om deze veranderingen in de context van verandering gedreven door antropogene invloeden te plaatsen zijn metingen op verschillende tijdschalen essentieel.

CV and Bibliography of Author

Curriculum Vitae

Lesley Salt was born on the 7th March 1986 in Nottingham, England. After attending secondary school in one of the villages *furthest* from any coastline in the UK, she attended the University of Southampton, where she studied Oceanography at an undergraduate level. Preferring the chemical aspect of Ocean sciences, her first Bachelors project examined the role of natural iron limitation on phytoplankton community structure around the Crozet Islands. After another year of biogeochemistry lectures, she completed her Masters project examining the carbonate system of the (Sub-) tropical Northeast Atlantic. In June 2008 she received her Masters degree from the University of Southampton and in the same month moved to the Netherlands to start the PhD project at the Royal Netherlands Institute for Sea Research. Having used two datasets collected by others at sea for her undergraduate and masters work, she has since taken every opportunity to be the one doing the sea-going work and has thus participated in 9 scientific cruises totaling 10 months at sea. At the time of writing Lesley is now working for the Centre National de la Recherche Scientifique at the Station Biologique de Roscoff, in France, in the Chimie Marine group of Dr. Yann Bozec.

Acknowledgements

“From the standpoint of daily life, however, there is one thing we do know: that we are here for the sake of each other - above all for those upon whose smile and wellbeing our own happiness depends, and also for the countless unknown souls with whose fate we are connected by a bond of sympathy. Many times a day I realize how much my own outer and inner life is built upon the labors of my fellow men, both living and dead, and how earnestly I must exert myself in order to give in return as much as I have received.”

Albert Einstein.

Firstly, and foremost, I would like to thank my promotor, Hein de Baar. Thank you for the opportunity to undertake this research, for your support and guidance throughout it and for the flexibility to follow the avenues of research that really interested me. It has been a hugely educative and fun adventure. Many additional thanks for facilitating a large amount of international travel in the name of science, and ironically, CO₂ research.

To my second promotor, Helmuth Thomas, thank you so much for the significant amount of time and work you have invested in this thesis, without your help I'm confident I would still be writing (Chapter 1...). Furthermore, I would like to thank you for your hospitality during my time in Canada, both in and outside of work. People are still impressed I managed to get an office **with** a window at Dal.

Over the past five years I've had the privilege to meet some wonderful people whom have all contributed something to my life or my thesis. In chronological order, firstly to Henk Zemmeling and Josje Snoek, whom made my introduction and integration into the NIOZ so easy, for which I am very grateful. To Steven van Heuven, whose mobile number is forever engrained in my brain since that first year of my PhD in which you helped me a ridiculous amount. I don't think I've ever had a more educative year and I am so grateful for it. Further thanks to Rob, Charlie, Maarten, Charlotte, Marie and Claire, whom all welcomed me to Texel and the NIOZ and made my first year on the island so much warmer and friendlier.

In Halifax, I owe a big thanks to CO₂-colleagues Elizabeth and Will, and also to Cayla, Hamish, and Kelly for the roadtrips, ice hockey games and all the fun times had. Here I will also add a big thanks to Jess and Teurai, for the encouragement, support, and much needed thesis-breaks throughout the years. (Hopefully the next time either of you ask if you can call me Dr.Salt yet, the answer will be yes!).

A very special thanks to all my housemates over the years who had to put up with my unorthodox working hours, unpredictable presence/absences, and severe arachnophobia. In Den Burg - Darci (and temporarily Niamh), I'm proud to still hold the record for 'quickest departure from the Potvis' with you. In Halifax - Jen, I still miss our summer evening swims in the lake and (too-) late night chats. On Texel - Sabine, thanks for all the delicious stuff you baked, Arno, thanks for being the most chilled out person, ever, and Olga, thanks for the general good mood you bring to the house (every second week ;)). The Potvis #6 has a history of good housemates, so I'm proud to be amongst them. In Groningen - Maaïke, Johan, Piedie and Lynn – I really enjoyed the strongbow-balcony, avond spelletjes, Read-Steady-Cook and an AH open past 8pm, even if it was only for a short time. The endless Frisian coffee at Emmastraat was definitely responsible for chapters 3 and 6! Occasional Den Hoorn housemate – Lenny, thank you so much for the bed and breakfast during my trips to Texel. I hope casa de Lenny, featuring the terracotta dome and world gin bar, opens somewhere near me one day.

I have also had the good fortune of participating in a total of 9 cruises throughout my time at the NIOZ. Each one stands out for various reasons, characterized largely by the people onboard. Here I would like to say a special thanks to all my cruise-buddies, who helped make those times so special. To Libby, with whom I spent ~4 months at sea from 03-2011 to 03-2012 – we were practically living together! Over the five years we've met in Paris, Punta Arenas, Las Palmas, Cape Town and Barcelona, I hope to keep this up for the next 5 years. To Nikki, my most recent CO₂ cruising buddy, thanks for making these past few months on Texel, in the Med, Black Sea, Istanbul and Lisbon so much fun. After two months of sharing a cabin with you, and so (so) many broken boundaries, its needless to say, I'll(mo) miss your face.

Additional thanks to the nutrients department at the NIOZ, for the wonderful job they do. Special thanks to Karel for all the help with oxygen measurements over the years and to Sharyn for all the additional help you end up giving us and for your cherished company onboard. To the guys in the workshop for all the help over the years and good times onboard, especially to Ruud, John, Leon, Jan Dirk and Edwin. Thank you to the crew of the Pelagia whom always make sailing so much fun, in particular Bert, Roel, Cor, Sjaak, Klaas, Alex, Ger, Jaap, Jose, Pieter, Rik, Freddy, Martijn, and Inno, whom I have had the pleasure to sail with a number of times now.

I owe a particularly huge thank you to my two paranimfs, whom have both helped me through the past years. To Astrid, my fellow PhD, office mate, and for two years, my only CO₂ colleague. You have been with me throughout this PhD and I like to think we have helped and counseled each other, and your companionship has meant a tremendous deal to me. I cannot thank you enough and I wish you, and your family, nothing but happiness and success in the future and hope I will be there to see it. To Maaïke, you have been my student, cruise-buddy, housemate, and friend and suffered with me through the hardest part of any PhD – the end. I will never forget all the support (and coffee and koek!!!) you gave me and I hope one day I can return the favour.

Finally, I'd like to thank Mum, Dad, Michelle and Matt (and Will). You have all witnessed the trials and tribulations over the past half-decade, with amusement, bemusement and more recently, possibly, some concern. Thank you all for giving me endless support, perspective, advice, a sense of humor, and a roof over my head, as and when needed.

Texel, 18th August, 2013.
